A half wave antenna such as the AEA Hot Rod or the MFJ copy of it works
well with no ground plane or trailing wire. The models I mentioned are
telescoping, so you can collapse them when not walking.

Hi Miguel,

You are quite right. Only an isotropic antenna can take all the
energy as only an isotropic could have transmitted it. The uniform
distribution and the spherical geometry force this solution even
though it is a practical impossibility.

The real question is, how did that energy get turned around to come
back?

>they are doing.

Firstly, to answer your question.

"SWR meters" like you buy off the shelf for HF/VHF/UHF are not commonly used at microwave frequencies, and you are talking about low end microwave frequencies.

The nearest equivalent would be to get a directional coupler (a four port device with IN, OUT, FORWARD and REFLECTED ports where the FORWARD and REFLECTED ports are a sample of the forward and reflected (RF) waves). You then measure the RF power at the FORWARD and REFLECTED ports using a wattmeter such as a bolometer wattmeter like the HP432A, and calculate the SWR. Used directional couplers are not very expensive, but power meters are and they (or the bolometer heads) are very sensitive to physical damage.

Second, so... now that you have measured / calculated SWR, what are you going to do with it. You haven't told us exactly what you are measuring, but SWR is caused by a multi-dimensional problem, and unless you know that a single adjustment will bring SWR into acceptable range, then SWR doesn't give you enough information.

It is almost all CB enthusiasts, most hams, and apparently some WiFi enthusiasts that think SWR gives them all the answers.

If you are genuinely interested in the technical aspects of transmission lines and antennas, picking a project at 2.4GHz is possibly a most difficult one for learning the principles because instrumentation is so expensive and components are so small physically (good and bad, but mainly bad).

Source record: 68208

thanks for your input guys. I havent been able to come online due to power outages caused by hurricane wilma.

anyway. the reed switch mentioned would work, but the distance is the issue. I currently have an rfid reader and passive tag, but they too work only within a few inches. What I need is for the device to be activated within 5 feet of the receiver and from my understanding a reed switch cant do that.

I know electronic toll payment systems seem to conserve battery, and thats what i need. Bascially I want to have a battery in the unit, but I dont want the battery to be connected until we're in that range. The reason passive devices dont work is because even though the antenna can provide an induced current, without a battery the tag doesnt have enough power to be able to transmit over say a few inches, let alone five feet. So we need battery in the transmitter. The user only carries a transmitter, so it doenst know when it is within range. I have a microcontroller that will transmit an ID as soon as it is powered up, but I dont want it to be on at all times, and I dont want a switch. I'll look into the "Hall Effect" now and see what its about.

Thanks again guys, keep it coming.

Source record: 68197

Thanks for the vote of confidence, but I don't have a ready answer.

Making an HF SWR meter that works well with 50 mW isn't trivial, and making an SWR meter that's accurate at 2.4 GHz isn't easy, either. Homebrewing either one, let alone the combination, requires considerable experience and skill, which Chris indicates he doesn't have, if even crudely accurate results are desired. Suggestions of a directional coupler or slotted line including detector, obtained complete from eBay or other surplus source, sound like the best ideas to me. Impedance information is available from the slotted line, but either will give enough information to allow adjusting for the best match.

Another way to adjust the match would be to put a 50 ohm pad -- 6 dB or so should be plenty of attenuation -- between the signal generator and antenna to insure a 50 ohm source impedance. Then the match can be adjusted for maximum field strength as indicated by a field strength meter. That avoids the need for an SWR meter or any calibration or reference. All you need are fairly decent pad and coax, both of which are easy to come by.

Hi Owen,

You are about to make this too difficult.

>The nearest equivalent would be to get a directional coupler (a four
>port device with IN, OUT, FORWARD and REFLECTED ports

Actually, only three ports are needed because reducing the reflected
power is the only thing that matters, not the determination of SWR.
Having said that, a four port is good too....

>using a wattmeter such as a bolometer wattmeter like

You don't need an expensive power detector either - just a receiver
with an s-meter. This is a glorified detector perhaps, but cheaper in
that you probably already have one. If you have the receiver but no
s-meter, there is probably some point that could be tapped to do the
same thing.

>picking a project at 2.4GHz is
>possibly a most difficult one for learning the principles because
>instrumentation is so expensive and components are so small physically
>(good and bad, but mainly bad).

I would say that if you stick with just the antenna, you can swap:
good and bad, but mainly good.

The wavelength dimensions allow for table top experimentation and
easily discarded mistakes.

Might look for items under "Farinon" - they made a 2 gig rig,
(PT-2000)? for telephone service , used 3cx100a5's and the rigs
were junk - but the ONE thing they had was a SWR/POWER meter , on
a panel - and many of those were salvaged to use with replacement
equipment. But, much of THAT is being retired, because of Cell sites
and other users are buying this equipment for access to those freqs
(replaceing with 6 GHz). Also, think Bird's meters are rated to 3 GHz
(I have a slug for 1 watt at 2000-2500 GHz), and thusly, also would
work with Dielectric, and their predicessor, Coaxial Dynamics meters
all of which are based on the BIRD 43 meters, physically, and electric-
ally. And, also Struthers 503 Military #'s TS-3686, A.K.A., URM-203
All (except for looks of the meter, are identical to the Bird 43and use
the same slugs as Bird manufactures (30 microamp movement).
Most likely, there are others, but these come to mind immediatly-

I hope none of the readers of this newsgroup are tempted to consider Reg's attitude or abrasiveness as typical of his countrymen. I recently returned from three weeks in Great Britain, ranging from southern England to the Isle of Skye in Scotland, and to southern and central Wales. Like on my previous three trips there, I was treated very well by some of the nicest people I know and have met. I, my wife, and son were taken in as house guests by two very good friends in different parts of the country.

I'm sure that if I'd displayed the sort of attitude toward the British that Reg constantly does toward Americans, I would have had an entirely different experience. But I'd rather concentrate on what good people have in common. And there are a lot of good people in all countries. As well as a few grumps, of course.

TRABEM wrote:
"I didn`t price it yet, but I need more technical information!"

There`s a better approach than high "Q" capacitors for a VLF loop. It`s been available since the year 1912 and much used soon after its invention.

Edwin H. Armstrong, 1890 - 1964 was radio`s most productive inventor. He invented regenerative control in 1912. I think he awakened his sister in the middle of the middle of the night screaming : "Eureka, I`ve found it!" or something to that effect. It wasn`t ubique for Howard Armstrong to discover things. Following controlled regeneration, he discovered the principle of the superhet in 1918, superregeneration in 1922, and the complete system of frequency modulation in 1933. He would battle RCA and Sarnoff for his entire life over control of his discoveries. I recall seeing a photo of the battery portable radio Howard built and gave his bride as a wedding present on an IEEE magazine cover.

Ever since 1912 there have been regenerative circuits introducing a fraction of a receiver`s output back into its input to enhance its amplification and sharpen its selectivity. Some of these are called "Q" multipliers.

A "Q" multiplier is an oscillator circuit which has its regenerative feedback adjusted just below the point of oscillation. It amplifies the signal many times and shrinks the apparent bandwidth the tuned circuit accepts. I`ve seen them used for reception of WWV at Boulder on 60 kHz and for other low frequencies. This seems easier than using super parts. Use some positive controlled feedback in the loop circuit. Adjust it for convenience.

Best regards, Richard Harrison, KB5WZI

Experience in electronics, especially when it comes to RF, no. However,
I do have considerable skill. I can solder pretty good and when it
comes to mechanical components, on a bad day I can cut things accurate
to +/- .003" on a good day +/- .001" or better. So with detailed
instructions and drawings I can build it as long as it isn't so complex
that it isn't worth the time.

Sounds easy enough if I knew what a 50 ohm pad was. I guess I should
open that ARRL Antenna book and start reading from the beginning.

Richard, in the absence of the specific purpose for the meter, I was guided by the request for an "SWR meter" and offered a solution that would do what most modern "SWR meters" will do, measure power in each direction.

It was (IMHO) a fairly complete answer to a functional equivalent that has the needed sensitivity, without regard to what features were essential to the unstated task.

I agree that for some purposes, a directional coupler with a detector may provide indication of the least reflected power, even if not an absolute measure. (You could probably buy a used coupler, xtal detector, termination and some attenuators for modest $$$ on Ebay, but it won't be as cheap as going and buying a commercial panel array for 2.4GHz if the objective is just to make a high gain antenna.)

I think that the discussion demonstrates that an instrument without appropriate knowledge isn't the full answer, not even half ways there.

As for the choice of a sandbox for exploration of antennas and transmission line principles, I think that VHF has a lot of merit for hobbyists.

Source record: 68205

Would it be possible that the question went by the following thing?

When we study directional or isotropic receiving antennas, we assume for example:

Punctual sources generating spherical wave fronts (convex) or infinitely far away punctual sources creating plane wave fronts for all the practical effects.
Under these conditions the receiving antennas are "outer" of the radiant sphere; this way, the effective area of a directional antenna represents a bigger external surface and it intercepts more energy than the corresponding to an isotropic antenna, then everything agrees with what we have learned on the directivity of the antennas, but in this example the conditions are inverted, now we don't have plane or convex fronts, we have concave fronts. The solution under the new conditions is different from the habitual one...

I think that the environment of the problem is similar that of the Kirchhoff law of thermal radiation: "a small sphere inside a radiant sphere".
I also think that the conditions of this problem could be similar (and therefore taken place artificially) to those of light`s receiver inside a luminous sphere.
In this case we proceed as when we study the entropía of an isolated system, in such a system the entropía can diminish, although that is not possible for the whole universe (I suppose this allows me to escape elegantly of Richard's question... ;> D

73´s for all, and thank you very much for your very interesting and instructive habitual postings.

Miguel Ghezzi (LU 6ETJ)

Spanish text for reference (withouts my translation errors).

¿Sería posible que la cuestion pasara por lo siguiente?:

Cuando estudiamos antenas receptoras direccionales o isotropicas asumimos por ejemplo:

Fuentes puntuales generando frentes de onda esféricos (convexos) o fuentes puntuales infinitamente alejadas que producen frentes de onda planos para todos los efectos practicos.
En estas condiciones las antenas receptoras están "fuera" de la esfera radiante; así, el área efectiva de una antena direccional representa una superficie exterior mayor e intercepta más energía que la correspondiente a una antena isotrópica, entonces todo concuerda con

lo que hemos aprendido sobre la directividad de las antenas, pero en este ejemplo las condiciones se invierten, ahora no tenemos frentes planos o convexos, sino de frentes cóncavos. La solución en las nuevas condiciones es diferente de la habitual...

Pienso que el entorno del problema es parecido al de la ley de Kirchhoff de la radiación térmica: "una pequeña esfera dentro de una esfera radiante".
También pienso que las condiciones de este problema pudieran ser similares (y por lo tanto producidas artificialmente), a las de un receptor de luz dentro de una esfera luminosa.
En este caso procedemos como cuando estudiamos la entropía de un sistema aislado, en tal sistema la entropía puede disminuir, aunque eso no sea posible para el universo entero (supongo que eso me permite huir elegantemnnte de la pregunta de Richard ;>D

73's para todos y muchas gracias por sus interesantes e instructivos escritos habituales.

That's a fair question. I am working on a few different antenna
designs, not my own design but other designs I find on the net. Such as
a wave guide antenna, collinear array and helix. In most cases part of
the design tells you to adjust a certain part till you have the lowest
SWR. That is what I plan to do with it. I am changing the designs
some, but only in a mechanical sense that I don't believe will have
anything but a positive effect on their electrical characteristics.
Such as in the wave guide, instead of using cans of some random size, I

found a copper pipe with a 3.5" ID that. Also instead of trying to mount a flat flange connector to a round tube (ugly), I have a method of directly attaching a coax cable to the tube with the center conductor being the radiating element.

>It is almost all CB enthusiasts, most hams, and apparently some WiFi

>(good and bad, but mainly bad).
>
>

due to physical limitations it is just a lot easier to work with the small stuff, and I do have the resources to make very accurate parts for the antennas. It's not that I can't work with the lower frequencies, larger antennas, it's just more work and takes up more workshop space. I may try a few at 440 though. Anything lower hz than that I will just buy an antenna and pay/con someone to mount it on my roof and be done with it.

Nevertheless, there are good reasons to use a coax connector.

How are you weatherproofing this antenna, and what type / length of
coax are you using?

The statement that measuring that the SWR is say, 3, doesn't tell you
what things to do to improve / fix it.

What adjustements do you have, are there matching screws near the
launch antenna to match it to the waveguide / space or are you going
to "dent tune" it? It may be worth looking for designs that
incorporate matching screws.

If you get that sorted, Richards suggestion of a simple coupler and
diode detector should be enough to match it up, but again I suggest
that learning how to calibrate a directional coupler at microwave
frequencies is jumping in the deep end. His other suggestion of a
simple field strength meter (perhaps another identical antenna +
detector) is a short cut to the performance you want without
considering the SWR as the lead to that outcome.

Use the passive receiver to power a transistor switch to activate the transmitter. You should be able to induce enough power in the unit to switch some kind of transistor switch connecting the battery to the second stage of the unit. You would have to be careful that only the proper signal activates the unit though.

Interesting Richard, thanks.

I read about these early pioneers years ago when I first became interested in ham radio and was fascinated by the history of early radio. There was a recent PBS program on the topic too, which I very much enjoyed.

Regenerative receivers are all that you say they are, and more. If it wasn't for the blasted gain control which has to be constantly twiddled, they would be more popular today I'm sure. Don't they have limited ability to separate the individual sidebands though, so they are more suited for AM and very narrow bandwidth CW?

I'm intrigued however.....

Lately I've been working with a QSD based receiver and am very impressed with it's simplicity and degree of performance. There are no non linear mixers, IF's, detectors or IF transformers, so high performance receivers are quite simple to build using this technique. In general, no rf stage is needed (or desired). All of the 'gain' comes after the detector, which is actually a high speed analog switch. But, recovering the audio without DSP based software (usually a sound card) is very difficult, needing large amounts of selective audio filters slowly tailor the audio response to an appropriate selectivity. Maybe some regeneration could be used to simplify this fairly complex analog filtering.

N7VE's high performance direct conversion receiver (the NC2030) has a highly detailed explanation of the post QSD audio using a hardware approach rather than the more typical computer/sound card approach.

It's good reading if you're interested in clean sounding cw without ringing and without over processed audio filtering crud mixed in..

While the job is simplified by modern op amps, it still takes a lot of stages of low Q filters to make the audio sound clean and crisp. A single high Q audio stage doesn't work well at all.

I wonder if regeneration could be implemented to simplify the complicated filtering needed to produce clean output from QSD based receiver?

I'm also wondering whether newer technology can automatically control the regeneration as needed, which might give a technological boost to an old concept and revive it in the process??!! It's happened before (example is newer high performance phasing type receivers are much easier to build with op amps and offer much higher performance in an

easier to build package).

I might try some regenerative feedback in some of the post detector audio stages next time i have the radio on the bench.

Thanks,

Tra

Thanks John,

I'll have a look. The newest Antenna Handbook I have is a 1950
version:>:

I've never been terribly impressed with the Leagues Antenna Handbook.
If the antenna section in the newer Radio Amateurs Handbook is any
indication, I probably won't buy one either. But, I'll have a look
see. The Reference section at the college library has a copy, so I'll
swing by and have a look to see if it's worth buying.

Ain't technology wonderful??? It took me less than 60 seconds to
search all the college libraries in New England because all the
offerings are online now! And, as luck would have it, I found one
right down the street (figuratively speaking).

Thanks for the suggestion, I'll check it out.

Regards,

T

I have a 4' section of LMR 400 with a female N connector on one end.
That connects to the pigtail adapter I have for my wifi pc card. It's
hard to describe with out a photo but the connection of the cable to the
wave guide will be weather tight. So the only way any moisture could
get in is through the far end of the copper pipe. If I ever permanently
mount this antenna, some plastic glued to the end of the pipe should
work fine.

In the case of the wave guide I think the length of the radiating element is the main adjustment. Also the distance from the back of the wave guide to the radiating element but I didn't do anything to make that adjustable, I just did the calculation and had my brother drill the hole with his milling machine, it should be with in +/- .001" of where I calculated it. I may decide to make it adjustable in future versions if this one works out good. The problem is it is hard to come by short lengths of 3 1/2" copper pipe, 3" is easier to come by but it is on the small side from the calculations I made.

For the collinear array, 2 of the 3 web sites I have found say to move a decoupling element up and down near the feed point to minimize SWR. They all do something a little different on each end of the antenna and I'm not sure if one is right, all are wrong, or it is just different ways of doing the same thing. Here are the 3 sites I have found on that design.

http://www.guerrilla.net/reference/antennas/2ghz_collinear_omni/
http://www.rason.org/Projects/collant/collant.htm
http://www.repeater-builder.com/antenna/wa6svt.html

For the helix in the ARRL Antenna book it says you have to match the impedance of the antenna to the coax and it says to do that you can adjust the spacing of the wire in the first turn to get it closer to the ground plane and use an SWR meter to know when you have it right. I'm reading this from page 19-29 of the 19th edition of the ARRL Antenna book. I think this design mod of the standard helix is from K6ZMW published in the June 1981 issue of QST.

Samuel Clemens (Mark Twain) is one of the characters in one of Harry Turtledove's excellent "alternate history" books. In the story, Clemens is living in San Francisco and has a dog named after the mayor, whom he detests. After a particularly frustrating meeting with the mayor, Clemens returns home and apologizes to the dog -- "When I named you," he says, "I thought I was insulting the mayor. But it turns out that I was insulting you."

Not that it helps you any, but I had to smile when reading your last sentence - I know K6ZMW from work. FYI, his work background is in the RF Design group for a satellite company so he does indeed know a thing or two about antennas.

Even there, bi-quad active filters have been doing this for those same
25 - 30 years, and quite smartly too.

You need to return to basics a la Robert Pease who does a lot of
informational multimedia for National Semi these days. He properly
offers that so much that has been handed over to binary twiddling is
such a step backwards to accomplishing a job better handled in the
linear domain.

If you can, manufacture/fabricate a catapult 6" in front of a fishing reel that has a closed faced spool that has 100 Yards of 6Lb monofilament line on the spool.
You might be able to get the local kid to sell you his catapult.

Fix them to a piece of wood with the reel at the rear of your lenght of wood "upside down" to the catapult. The reel can be fixed on the wood with insulting tape on the reel feet. The catapult needs fixing on the wood, at the end. Make a fixing to steady it up on the wooden bar. The catapult hand grip goes below the wooden bar.

If you use a lenght of wood long enough to support a stock piece that you can pull into your shoulder, this will help in making the target alot easier to "hit" and will give support at the rear, the catapult handle giving support at the front, thus enableing your other hand to pull the catapult rubber back.

After tying the line to the weight, (use a pear shaped lead) place the weight in the catapult pouch, release the bail pin and the lead weight is shot over the tree limb. After reaching and acheiving the desired target!! remove the lead weight, tie a nylon cord to it and "reel the line back in"

Remove line after reeling back in, put assembly away. Tie your dogbone or insulating piece that's on the end of your wire to the cord, pull your nylon cord back and anchor to anything usable. Jobs a good un. ezy pezy
Sounds dead long winded, but simple really. Dave

> this, I certainly don't now :)

SWR isn't the only important thing to consider. SWR BANDWIDTH is probably more important. once you have it established at its lowest point, you then have to measure the 3 DB dropoff points to determine antenna efficiency. the narrower this band, the higher the antenna efficiency (within limits)

However, given the nature of WiFi signals (> 500 Mhz wide), this presents some unusual problems to the mix: balancing Antena efficiency without losing performance.

That turns out to be complicated (more so considering that you are working in the microwave bands here and very small changes in antenna length/width can have huge impacts on operation).

Now, I have a fair amount of knowledge vis a vis antenna design, but I am, by no means, an expert on them (even less for microwave designs). I would suggest that one check out a few of the ARRL books on antenna design.

Hi Richard,

>>In general, no rf stage is needed (or desired).
>
>In general, no rf stage has been designed into a receiver for a
>quarter century. Hence touting it as a hallmark is rather pedestrian.
>

True, but few of the inexpensive receivers that operate without rf stages perform very well. And I don't know any commercial application that uses regenerative feedback to gain selectivity in a real world receiver application. Typically, receivers that perform well have many (post detector) poles of modest Q filter stages to prevent undesirable features such as ringing. This uses alot of hardware, especially precision resistors and capacitors.

Yes, scaf filters are relatively clean, but it's still a multichip solution needing quite a few R's and C's.

>>But, recovering the audio without DSP based software (usually

>such a step backwards to accomplishing a job better handled in the
>linear domain.
>

There's room for both. KK7P's single chip digital solution to processing the I and Q from the detector to the speaker is quite attractive. It offers the potential of high performance while freeing us from the sound card/computer leash (and the big three Japanese corportions that dominate the ham radio transceiver industry) that currently restrains us. It's the missing link that makes high performance digital solutions into a 'free standing' piece of hardware.

It appears to me that DSP uses a great deal of power to do the job though. In practical terms, what we save in portability and bulk with

a single chip digital solution might be minimal because we have to carry bigger batteries to make it happen in a portable environment.

Like I said, there's room for both...and small changes in hardware availability constantly move the equation regarding 'what's best for me' in varying directions.

I prefer to know both digital and analog worlds though instead of limiting myself by only knowing 1 possible option.

Since the original responder wrote about regenerative methods however, I will keep my eye peeled for a practical means to implement it with modern technology components. If it was implemented in the post detector audio processing, it might minimize hardware needed to achieve high selectivity with clean sounding audio. I thank him for the reality check regarding this possibly useful method.

Regards,

T

True, but because the OP was looking for an SWR meter I assumed he had some sort of signal source. If he doesn't, neither an SWR meter nor any other of the suggested methods will be of much use.

Hello Richard (my middle name is Ricardo = Richard. We are
"Tocayos"...)

Richard wrote:

> Can there be an escape? Ron's question was posed with an impossible
> proposition. A collapsing sphere of electromagnetic energy?

Ron wrote:

> Assume an incoming rf signal has exactly the same strength in all 3
> dimensions i.e., completely omnidirectional.

If I have understood well Ron's question...

What about a number tending (spreading?, going to? - a limit, as in
calculus) to infinite, of coherent punctual electromagnetic identical
sources on the inner surface of a sphere with testing antennas in
center of it? (I think it isn't necessary neither coherence or
identicals sources. Noise sources fix well in my interpretation of the
concept that (I believe) Ron it wanted expose to us).

Can it these conditions to be thought?
Could it be simulated with an electromagnetic CAD as FEMLAB?
Are they agree with Ron question?

What do you say Ron?

Miguel Ghezzi (LU 6ETJ)

PS: I have another physical doubt, if you can help me.
Can a real DC current radiate electromagnetic energy?.
It is not captious or cheat question. I think yes, but I don't want to
condition your answers with my hypotesis.

Thank you in advance for your answers.

Richard escribió:

> Puede haber una salida?. La pregunta de Ron fue presentada con
> proposicion imposible. Una esfera de energía electromagnetica colapsandose?

Ron escribio:

> Asuma una señal de rf entrante que tiene exactamente la misma intensidad en las tres
dimensioes, por ej, que es completamente omnidireccional.

Si he comprendido bien la pregunta de Ron...

Que tal un numero tendiendo a infinito de fuentes electromagneticas puntuales identicas, situadas sobre la superficie interior de una esfera y las antenas de prueba en el centro de la misma? (creo que no es necesaria ni coherencia ni fuentes identicas, fuentes de ruido van bien en mi interpretacion del concepto que (creo) que Ron quiso presentarnos.

Pueden estas condiciones ser pensadas?
Podrian simularse en un CAD de electromagnetismo, tal como FEMLAB?
Estan ellas de acuerdo con la pregunta de Ron?

Que dices tu Ron?

Miguel Ghezzi (LU 6ETJ)

PS: Tengo otra duda física si ustedes pueden ayudarme. Puede una CC real irradiar energía electromagnetica?
No es una pregunta capciosa ni una broma. Yo creo que si, pero no quiero condicionar sus respuestas con mi hipotesis.

Agradezco sus respuestas por adelantado.

On all but the smallest of scales, the sky is quite uniform in its
luminosity. It can hardly be described as a "collapsing sphere"; not
even from the point of view of a geocentric model of the universe.

Hi Miguel,

A "real" DC current?

Yes.

A "real" DC current (at some point in time) starts - and stops. It is at each of these two points that the step change offers radiation. The "time" it takes to go from one level to the other defines that frequency, and its harmonics.

A "perfect" DC current has always been on, and will always be on. No change, no radiation.

Hi Jim,

Perhaps not, but "quite uniform" is rather in the eye of the beholder.
When I take panagraphic photographs (a broad scale), it is quite
evident that the uniformity is not very uniform. Another variable is
that polarization is not very uniform either (which, photographically
may be saying the same thing).

The eye is a wonderful device, but not very precise.

Hi, all folks and Dear Richard (Is right this salutation?)

Thanks for your patience to me...

Imagine a simple DC generator in steady state, the closing circuit (sure, with a serie resistance, no short), forms a physical loop, the current travel accross it in a uniform circular movement, therefore charges have a centripet acceleration => charges accelerated = electromagnétic radiation.

Electron orbiting nucleus problem -> quantum theory solution.

Am I in the correct way?. DC current produce electromagnetic radiation (on solenoid more, of course)?

I never read something in such a sense (except in atomic theory, of course), but I find reasonable to suppose it.

Thanks in advance

Miguel Ghezzi (LU 6ETJ)

Hola a todos y estimado Richard. (es correcto saludar asi?)

Gracias por su paciencia.

Imagine un simple generador de CC en regimen estacionario, el circuito que lo cierra (por supuesto con una resitenci, no en corto) forma un lazo físico. La corriente viaja a traves de el en un movimiento circular uniforme, por lo tanto las cargas poseen una aceleracion centripeta => cargas aceleradas = radiacion electromagnetica...

El problema del electron orbitando el nucleo -> solucion de la teoria cuantica.

Estoy en lo correcto? La corriente continua produce radiacion electromagnetica (mas en un solenoide, por supuesto)?

Nunca lei nada en tal sentido (excepto en la teoria atomica, por supuesto) pero me parece razonable suponerlo

Miguel Ghezzi (LU 6ETJ)

2984. Re: Antenna gain question

Newsgroup: rec.radio.amateur.antenna
Date: 2005-10-31 21:57:46 UTC
From: Ron <rmrippy@hotmail.com>
Message-ID: <urw9f.38$Ea3.18088@twister.southeast.rr.com>
Source record: 68082

Question (repeated here for convenience):

Assume a receiving antenna is in the center of a sphere and the
received signal is coming in equal amounts from all points on the
surface of the sphere. Which receiving antenna would capture more
power, an omni or a high gain beam? There are no noise and no losses.

First, thanks for all the comments. They have helped me better
understand the answer. I am leaning toward the belief that the omni
(isotropic) antenna would capture more power and, as odd as it may
seem, would have more gain than a high gain beam (or any other
directional antenna for that matter). Here is my thinking:

This is a very unusual RF field. Usually the field is assumed to be
planar with coherent rays - then antennas behave as expected. But this
field originates uniformly from all points on the surface of a sphere.
It does not spread but converges at the focal point of the sphere.

An isotropic antenna placed at the focal point would collect all of
the rays whereas a directional antenna at would not.

Therefore, in this particular situation, the isotropic would have
higher gain and capture more power than any directional antenna.

Please correct me if I am wrong.

Hi Miguel,

It is fine.

>Imagine a simple DC generator in steady state, the closing circuit
>(sure, with a serie resistance, no short), forms a physical loop, the
>current travel accross it in a uniform circular movement, therefore
>charges have a centripet acceleration =3D> charges accelerated =3D
>electromagn=E9tic radiation.

You are using acceleration in its usual sense. Unfortunately, it is
based on a poor description for radiation. It is a poor description
in English, or any language.

>Electron orbiting nucleus problem -> quantum theory solution.

Circular motion is always acceleration, and orbital electrons are
always in circular motion. They are not always radiating. This one
observation is enough to invalidate the general description of
accelerating electrons causing radiation (it takes more than that).

An orbital electron only radiates when it changes orbital levels to a
LOWER orbit. Read about deBroglie waves. When an Hydrogen electron
in the 3rd orbital falls (acceleration) to the 2nd orbital, it
radiates a photon with a wavelength of 653 nM. You see this every
night with Neon signs.

>Am I in the correct way?. DC current produce electromagnetic radiation
>(on solenoid more, of course)?

No.

>I never read something in such a sense (except in atomic theory, of
>course), but I find reasonable to suppose it.

Reasonable, as I have described above, but not logical.

Well, for one thing, your model assumes something which does not and
cannot exist. It assumes the existence of an actual isotropic
antenna. Such cannot actually be constructed - there's no way to get
a truly omnidirectional radiation pattern without violating Maxwell's
equations.

I suspect that you'll find the same problem existing, in the reverse
direction, if you try to construct the sort of RF field you're talking
about. If you try to specify the E-plane and H-plane field components
for a uniform, arriving-from-all-points-of-a-sphere field, I believe
that you'll find that you can't achieve your goal: there will always
be "seams" (abrupt discontinuities or cancellations) in the field
components in some directions.

Uniformly inward, outward, or both?

> It does not spread but converges at the focal point of the sphere.

By focal point of the sphere do you mean the center of the sphere? How
big of a sphere are we talking about, and where is the antenna in
relation to the sphere?

> An isotropic antenna placed at the focal point would collect all of the
> rays whereas a directional antenna at would not.

Probably.

> Therefore, in this particular situation, the isotropic would have higher
> gain and capture more power than any directional antenna.

Not according to the accepted use of the term 'gain' in connection with
antennas.

> Please correct me if I am wrong.
>
> Ron, W4TQT

In the instance you describe, the antenna with gain will pick up less
signal than an antenna without gain. The gain antenna will be able to
sense signal arriving from only a fraction of the sphere, whereas the
isotropic antenna responds to signals arriving from the entire 4-pi

sphere. Therefore, the antenna with less gain produces the greater signal level. But this should often be the case when a directional antenna is pointed away from most of the signal. The omni, on the other hand, is 'pointed toward' this particular signal in all directions.

Out of curiosity, what kind of signal source are you interested in?

Why not just use the rod and reel? Admittedly some can throw farther
than they can cast. OTOH in the city of Midland it is illegal to use
said catapult, bow, or other mechanical means of throwing things. At
least they've not outlawed the use of the rod and reel. Myself, I
like a good cross bow. OTOH you'd need a lot more than a 100 yards of
monofilament.<:-))

Still it's not problem here as I live out in the country.

I doubt there are very many people who can either throw, or cast a line, at 70 feet, over a particular branch of a rather densely packed conifer tree. I can do it, however, with a slingshot. A bow or crossbow would be even better, I'll admit.

This was only a mental exercise to help me visualize the concept of
gain. No resemblance to a real antenna or RF field was intended.
Thinking about it has helped me understand what antenna gain is
(assuming my conclusions are correct). And that's all it was supposed
to do. I hope it has helped someone else to do the same.

> LOWER orbit.

His question was about a conductive loop RF antenna.
RF radiation from an antenna comes from free electrons. Their
associated photon energy levels are correlated to the frequency
of the excitation energy, not to changes in atomic orbits.

Hi Richard

Thank you for your answer.

You are quite right Richard, this is the great postulate of Bohr, but from:

physics.indiana.edu/~sg/p641/chap2.ps

I have extracted this paragraph (rememember that I did study from books in spanish, so I had to search the web to find a suitable english references.)

"...Some physicists of the time did not at first believe in Rutherford's model
of the atom because, classically, such a model is unstable. The argument is as
follows: Electrons in orbits around a nucleus undergo acceleration. But accelerating charged particles emit electromagnetic radiation, losing energy. Therefore,
electrons orbiting a nucleus should lose energy and spiral into nucleus.
Then in 1913 Bohr solved the problem by simply postulating that electrons
move around the nucleus in certain stationary orbits without emitting radiation.
According to Bohr¡s model electrons emit radiation as photons only when making
a transition from one stationary orbit with a higher energy to another stationary
orbit with a lower energy."

Bohr's postulate would not invalidate the postulate of the classic electromagnetism that a accelerated charge irradiates energy in classical conditions. Their postulate refers to an electron in an atomic orbital, a typical quantum situation, the electrons in a circular wire would be being part of a classic macroscopic system, (I think).
In such a case, would not emit energy, according to that pointed out in the cited Indiana's university text ?

I can think a more elaborated example of Direct Current to avoid derived issues of the electronic movement in a complicated crystalline structure: An electron (or current of electrons) inside a magnetic field in the vacuum, just as in a cyclotron...

Would it be rightfully an Direct Current?.
Does it fulfill the postulates of the classic physics?
Does it irradiate electromagnetic energy?

For these reasons, I think that DC irradiates electromagnetic energy (a very, very, very little quantity, of course. This ponderings rises in my mind from a friend's question about an eternal current in a superconductor ring.

What do you think about?

Thank you very much for your corrections to my translations...

Miguel Ghezzi (LU 6ETJ)

Hola Richard.

Gracias por tu respuesta.

Tienes razon Richard, ese es el gran postulado de Bohr, pero de:

physics.indiana.edu/~sg/p641/chap2.ps

Extraje este parrafo (recuerda que yo estudie de libros en espaniol de manera que tuve que buscar en la web para encontrar referencias adecuadas en ingles).

[Original english text not translated...]

El postulado de Bohr no invalidaría los postulados del electromagnetismo clasico que una carga acelereada irradia energia en condiciones clasicas. su postulado se refiere a un electron en un orbital atomico, una típica situacion cuantica. Los electrones en un conductor circular estarían formando parte de un sistema macroscopico clasico, creo.
En tal caso, no emitirian energia de acuerdo a lo senialado en el texto de la Universidad de Indiana citado?
Puedo pensar en un ejemplo mas elaborado de corriente continua para evitar las cuestiones derivadas del movimiento electronico en una complicada estructura cristalina: Un electron (o corriente de electrones) dentro de un campo magnetico en el vacio, como en un ciclotron.

Sería legitimamente una corriente conínua?
Cumple con los postulados de la fisica clasica?
Irradia energia electromagnetica?

Por estas razones creo que una CC irradia energia electromagnetica (una muy, muy, muy pequenia cantidad, por supuesto). Estas cavilaciones surgen en mi mente a partir de la pregunta de un amigo acerca de una corriente eterna en un anillo superconductor.

Que piensas?

Miguel Ghezzi (LU 6ETJ)

Hi Miguel,

You do very well with English.

If you wish to be very, very, very specific, then yes DC will radiate.

Let's take something a little more practical than a cyclotron - the monitor you are looking at to read this. The CRT is accelerating an electron to strike a phosphor to illuminate a pixel. We will neglect that light radiation as not being part of the discussion.

That electron will be accelerated by a field of some 20KV. What is its frequency?
34.6 exaHertz
the wavelength of roughly 1/10 the distance of an electron orbit around a Hydrogen atom.

Now, for something completely different. Does a car driving 40 KM/Hour down the road radiate? If you wish to be very, very, very specific, then yes the car will radiate by the same principle at
5 zetta-yottaHertz

I've been using my old Bear hunting bow, and rubber tipped small game arrows with 20 lb fishing line for years. Works great, even though the neighbors think I'm crazy. After I get the line where I want it, I cut the line freeing the arrow and tie on a 1 oz. bullet sinker and pull the line up over the tree limbs that are 'extra' till the sinker is only over the target tree limb and then just drop the line and sinker. Works perfect.

One more thing: Before thinking about all this, I always thought that since a high gain antenna has a narrower beam than a lower gain antenna, the high gain antenna "sees" a smaller part of the incoming field. I now believe this is wrong. The higher gain antenna sees a larger field area. But as the antenna is rotated the sum of all the rays decreases faster than if there were fewer of them. This is probably due to the rays from the outer edge of the field causing a faster decrease in the coherent summation of all rays than the closer in rays. Of course, as the rotation is continued, many (but not as many) of the rays add coherently again, giving rise to the side lobes.

Hopefully no one else was led to that belief by the exercise.

Such a claim might be remotely plausible were it not for the fact that
rotating a directional antenna does not "coherently sum all the rays".
That's where the argument completely falls to the ground, as Monty
Python might say.

Seems to me, a receiving Yagi causes constructive interference
in the forward direction and destructive interference in the
rearward direction.

But does it seem the antenna causes destructive interference when the forward direction of the radiation is toward the rearward direction of the antenna, or does it seem like it causes constructive interference when the forward direction of the radiation is away from the rearward direction of the antenna....and if so, what does that have to do with "coherently summing all the rays by rotating the antenna"? Just wondering.

"Coherently summing" certainly doesn't imply that interference
is only constructive. An antenna is "coherently summing" all
the rays it receives no matter what direction it is pointed.

Not sure what you mean by "focal point", but the best any antenna can do is to intercept half the energy in some equivalent cross-sectional area of an impinging field. It does this when connected to a matched load.

When an antenna intercepts one watt from a field having a power density of one watt per square meter, it's said to have an "effective aperture" or "capture area" of one square meter. The higher the gain of an antenna in some particular direction, the larger its effective aperture in that direction. Consequently, a high gain antenna would "capture" more power from a wave arriving in its favored direction than an isotropic antenna would. It would, of course, capture less from other directions, but assuming equal efficiency, both antennas would capture equal amounts overall.

The "capture area" isn't some physical region with boundaries -- it's simply a way of expressing how much power is extracted from a field having a given power density. In other words, it's just another way of expressing antenna gain.

Has someone got a good definition of coherent.

I thought that it implied "same phase", as in a coherent source is one where all rays, photons, whatever are in phase. An antenna may well receive rays from a single source that are not in phase.

If that is the case, what is "coherent summing". Is it trying to refer to a function that adds components algebraically, ie having regard for the magnitude and phase?

Why is light a better vehicle for explanation of an antenna that radio waves?

HamPoll is here in order to give amateurs a chance to speak for themselves, and in time to provide reasonably accurate and significant polling data on a variety of issues related to the amateur radio service.

You are welcome to browse the polling data we have, but we especially encourage US amateurs visiting here to register with thier callsign and vote in the HamPoll Polling Station.

Whether you come to browse, to discuss or submit new polls, or to tender your vote, be sure to visit regularly as new polls are included from time to time, and the poll data changes as more hams participate day to day.

Stop by at: http://www.hampoll.com

The way I've always seen it used in this context is meaning "exactly the same frequency". They don't have to be in phase, but the same-frequency requirement implies that the phase relationship wouldn't change with time.

This is consistent with the definition from _Merriam Webster's Collegiate Dictionary_: "relating to or composed of waves having a constant difference in phase <~light>".

How to install an antenna

Here is another letter from Elmer A. Hamoprater titled
"how 2 put up an antenner"

Please note that we did not correct his spelling or edit his letter in any way.
Our Spell Check program crashes when used on Elmer's letters!
It is printed here below exactly as sent to us!
hay agin mi ham raydio frend.
lik i pramised bfor hear is mi letur tellin ya how 2 put up an
antenner.
tha first theng i need ta say is it shor is hard wurk puttin up an
antenner.
ya need a lota plannin an fixin bfor ya can git starded.
2 of tha mos emportent thengs ta hav is a gud test dawg ana gud pare
uf wyre cuters..
mi test dawges name is yep.
i named hem that caws thates whut he duz whin he fines tha wrong wyre
fur mi antenner.
i ownly use won kind uf antenner wyre caws i kin fine it purty esey
arond whur i liv.
it downt cost me nuttin ecept fur all tha wawkin an runnin me an yep
mi dawg gota du.
we start kinda earlie en tha mornin hikin over tha hill tu mi
naybors land
wher i git tha wyre fur mi antenner.
mi naybors gota lota land whur he kepes hes couws an won bull
fenced en.
an all tha wey arond it on tha fence he keeps nyce nue shiny wyre thet i
make mi antenners owt uf.
i kin awl ways git awl tha wyre i need thayer caws ever tyme i git sum
mi naybor puts mor
up betwen tha post.
i al so git mi ensulayters frum ofa tha posts ta use own mi
antenners.
gettin this wyre kin be awful dangrous to yur helth caws uf tha bull so ya
gota keepa sharp lookowt furim.
bout tha tyme we git closeta tha fence i needa little forta fyin sow i reech
bak in mi bak pac and pul owt
o i for got to tel ya bout tha bac pac.
bfor i leve mi shak i git mi ol ladiy to pac me an yep up sumpin to
eet an drenk.

wel i git mi dawg yep a biskit an im sorta thirstee sow owt she cums
mi jar uf sippin licker.
i no im gonna needa lota corage ta git tha wyre owt frum unner that bulls nose
sow i opener up and take abowt
8 swallers.
mi dowg yep es lookin up at tha jar sow i no he mus be needin a liddle corage
2 sow i reech bak in mi bac pac
pull owt anuther biskit and soke it gud withe the sippin whicker an
givit toim.
doun it gos weth won gulpe ana coupla sekons latur bothe ears stan strate up
an i no mi dawg es rediy to wurk.
he trots ovur ta tha furst post he cums tu hikes hes hin
lig an letser fli.
if he lets owt a yep an is nocked backards then i no thet tha wyre is hot ans
tha wrong wyre fer mi antenner.
this is why its emportunt ta hava gud test dawg.
yeps name sure is fittin fer im.
whin yep finaly stops yeppin an gits up we go ta a difrunt part uf tha fense
and yep dum ol dawg testes it agin.
thes tyme he jus sorta luoks at me an grins an i no tha wyre is gud wire fur
my antenner. smart dawg mi yep.
i reech out an kut tha wyre weth mi wyre cuters an grabit an me an ol yep start runnin
as hard as we kin tawards home hopein tha bull
was busy. sumtymes i git forti er fity fut ata tyme lik
thes.
we finely git tu tha shak an ol yep plops doun on tha botum step an i pul
ouwt my jar uf swippin clicker an
biskits an set a spell wunderin how ime gonna git mi nu wyre up in
tha trees.
im knot tu keen on climin trees or enything vury hi but ol yep jest luvs ta
clime. he wun a contest a while bak at
tha cownty fare fer climin an beet dawgs frum al ovor tha
place.
i now had an idear abowt how to git mi nu wyre up in tha tree sow i maid up mi mind
tu let yep hav sume fun sow i wokeim up.
he jumped up weth won ear up an won doun an starded ta wag his tayal. i think
he new what wus gonna happin.
smart dawg mi yep.
i got tha nu wyre an tyed it tu his tayal an poyned tu tha tree an yelled up
yep an he lit owt lyke greezed
litenin up tha syde uf tha tree weth bark justa fliyin.
he got abowt tin fut up an straduled tha furst lim an held own an
barked doun at me.
i new whut he wantid. mor corage.
i ran an got anuther biskit an soked it gud frum mi jar an chunked
it up tuim.
he cawt it in mid air an swollered it hole an ina flash he wuz own
hes way agin.
i recon tha tree musta ben abowt therty er forety fut tall an yep brok alota
lims own his way up tu tha top.

he finaliy got tu tha last lim at tha top an grabed hold weth bowth paws
an hunge own fer deer lyfe.
he wuz sum syte hangin frum tha lim way up ther weth mi nu antenner wyre
tyed tu his tayal.
wel it jest kame tu me thet ol yep wuz a gud tree climin dawg but thare
wuz 1 problem i had fergot.
he did ent no how ta git doun.
dum dawg mi yep.
wel i did ent wont im ta fall sow up tha tree i wint after i fenished mi jar of
sippin slisker caws i waddent tu keen
on climin..
when i reeched him i tuk tha nu wyre ofa his tayal an tyed it tu tha lim
an grabed him an put
him arown mi nek an starded doun tha tree.
i got tu tha growne an ol yep leeped frum mi bak an ran unner tha
shak.
smart dawg mi yep.
i loked up at mi bran nu antenner wyre hangin frum tha tallist tree i had
an then i real lized that
tha end uf it wuz abowt therty fuut up tha tree.
dang it.
here yep. whure is zat dawg.

it shor is hard wurk puttin up an antenner.

ey will right mor latur whin i git anuther pen

I agree.

By "focal point" I meant the center of the sphere where the rays
converge and where the antenna would be located.

In the unusual field defined in my example, the algebraic sum of all
the rays collected by the antenna would be higher in the isotropic
antenna than a high gain antenna. Think of the front to back ratio of
the high gain antenna which would result in very little output from
the rays behind and on the sides of the antenna. Therefore, the
isotropic would have a higher output which is indicative of higher gain.

I do not understand what you mean by "capture equal amounts overall".
Energy which may strike the antenna but does not result in any output
power isn't "captured".

> The "capture area" isn't some physical region with boundaries -- it's

How about a dish antenna? Isn't the capture area proportional to the
physical area of the dish?

I receive rays from WTAW that are sometimes in phase and sometimes not over a period of mere seconds. Earth's atmosphere seems to be a coherence killer.

Thanks Cecil and Roy... obviously my understanding (in-phase) was just
too narrow. I did find Roy's text more coherent!

Interesting to Google for the use of the term, and it appears to be
very loosely used... I guess to some extent because of its roots in
common language and the ordinary meaning of the word.

The same amount of energy is incident upon both antennas at
the center of the sphere. Maybe the high-gain antenna re-
radiates more energy than the isotropic?

Roy, W7EL wrote:
"They don`t have to be in phase, but the same frequency requirement implies that the phase relationship wouldn`t change with time."

Definitions of terms like "coherent" change with time.

Slectromagnetic waves are described as "plane-polarized waves" because variations in their electric and magnetic fields can be represented by vectors that lie in a plane. It is proven that light waves and radio waves are of the same sort but differ in frequency.

The first reference I ever saw of a coherent wave was a description of light from a laser. It meant the waves started and stopped together passing through zero at the same time.

Light waves are emitted by molecules or atoms that are excited by thermal or electrical means. These molecules or atoms are randomly positioned and so are the waves generated by the energy level changes within them. Phase and polarization are thus random in light produced by ordinary light sources. Light is coherent from a laser.

A photon can interact with an atom in a laser if its energy exactly matches the energy difference (delta E) between two allowed (by Bohr) energy states for the atom, it can cause a transition. This is called a stimulated transition.

Best regards, Richard Harrison, KB5WZI

I have to admit, I was looking at this a more of a problem of equal signals arriving from all directions, rather than at the middle of some sort of convergence. Of course, any rays reaching the center would continue on through, Cecil's unique theories notwithstanding. I don't have the spare time to contemplate what the end field distribution would be like at the center of the antenna or its periphery.

It's not obvious to me why that would be.

> Think of the front to back ratio of the high
> gain antenna which would result in very little output from the rays
> behind and on the sides of the antenna.

That's true. But the output would be higher in reponse to the rays arriving from the front. We call that "gain". Another way to express it is that it intercepts a field from a larger area of the wave front.

> Therefore, the isotropic would
> have a higher output which is indicative of higher gain.

You're right that higher output means higher gain. I maintain that both antennas have the same total gain, i.e., the same total interception of power from all directions. This follows directly from the reciprocity principle.

> I do not understand what you mean by "capture equal amounts overall".
> Energy which may strike the antenna but does not result in any output

> power isn't "captured".

The field you're creating comes from something and goes somewhere. If
you subtract the total amount going from the total amount generated,
you'll get the amount dissipated in the load connected to the antenna.
That is the amount of energy "captured" or "intercepted" by the antenna.
And that's what I thought you were talking about all along.

>> The "capture area" isn't some physical region with boundaries -- it's

Indeed it is, in the front direction. But how about a dipole? The
capture area (or gain) broadside to an infinitesimal dipole is just
slightly less than that of a half wavelength dipole. And wire diameter
makes almost no difference.

Sorry, the theoretical construct is just a little too much like
Calvinball to hold my interest. I'll bow out now. Best luck in sorting
it out.

> continue on through, Cecil's unique theories notwithstanding.

The way the incoming fields were defined, they all converge
at a point in the center of the sphere. Presumably, that's
where the isotropic antenna is located. Replacing the isotropic
with a Yagi whose feedpoint is logically located at the point
of convergence means that any part of the field that doesn't
encounter parts of the Yagi before the point of convergence will
converge at the feedpoint on the driven element of the Yagi in
a defaulting isotropic manner. Given the definition of the
spherical fields, there is no part of the fields that will not
encounter the Yagi.

Therefore, the isotropic and the Yagi receive the same amount of
energy, i.e. all that exists in the spherical fields. Any energy
not received by the Yagi beam elements is received in a default-
isotropic mode at the Yagi feedpoint.

The source of radiation was not described; only its distribution. It was like being surrounded isotropically by radio sources - not unlike the 3 K background. But there are other sources which pretty well surround us as well.

I knew I had this, but couldn't find it when I read the post then when I found it, I couldn't remember where I saw the question.

I found it, I found it:

Icoms have the same voltage that Cecil refers to and here is a "decoder". I believe it identifies all pre-WARC _and_ WARC bands except 12 meters (the rationale being that antenna tuners typically can tune 10 & 12 with the same components).

For your conceptual purposes, your question would be similar to this?:

In a deep focal point of parabolic dish two antenns are mounted...

Which of them it does pick up more energy?

An antenna with 180 degree beamwidht or an highly directional antenna
with 0,1 degree beamwidth (both pointed to dish, of course)?

(In focal point of dish there are convergent frontwaves also). (We
could think in a sperical dish, also).

OK, sometimes I lose the context. If the radiation is arriving
isotopically, it doesn't matter which direction the Yagi is
pointed (as I inferred from what you said).

But arriving isotropic radiation would all converge at a point.
If a plumber's delight Yagi driven element is centered on that
point, it would receive all the radiation in a default-isotropic
mode.

Ron, W4TQT wrote:
"How about a dish antenna?"

The parabolic reflector converts the spherical waves of its radiator at the focus of the parabola into a plane wave of uniform phase across the mouth or aperture of the parabola. Mouth ans aperture are syninymous when applied to parabolic, lens, and horn antennas. Rays enter and exit parallel but reflect through the focal point. Reciprocity rules and the path through the antenna is the same, coming or going. The parabolic reflector antenna sends and receives to and from a familiar spot on its axis and at a distance. It is inoperative outside the spot and its path of travel. The larger the parabola, the smaller the diameter of the spot, and the higher the power gain.

The beamwidth of a large circular aperture such as a parabolic antenna is inversely proportional to its diameter in wavelengths. The total field radiated by a arabola is the vector sum of the fields generated by the elementary areas making up the aperture or mouth of the parabola. The directive gain of a parabola antenna is directly proportional to the area of its mouth and inversely proportional to the wavelength squared. See 1955 Terman page 899, equation (23-28) as pointed out at the bottom of page 911.

Best regards, Richard Harrison, KB5WZI

I think Roy pretty well nailed the answer. An interesting result - both antennas producing equal signals. I'd like to check that by comparing a dipole to an isotropic in such a field. I assume the results would be the same. Again, an interesting result. But you both bring some interesting points.

3042. 900MHz antenna at sea surface

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-02 20:09:28 UTC
From: jmorash <jmorash@gmail.com>
Message-ID: <1130962168.655457.263840@f14g2000cwb.googlegroups.com>
Source record: 68239

Hi folks,

I've got some background in EE, but know very little about antennas (though I have a copy of the ARRL Antenna Book I'm reading now), so please bear with me if these are newbie questions.

I need to communicate with a device floating on the surface of the ocean, at ranges of several miles or more, using a 900MHz radio link. Vertically polarized seems to be the way to go, to get true omnidirectional reception. My shore- or ship-side antenna can easily be placed 20' or more above the surface of the water, and I can use an off-the-shelf, moderate gain (5-6 dB) product with a nice fiberglass radome, etc.

It's the remote side that's the problem. I need to fabricate my own antenna, rather than buying one, for packaging and waterproofing reasons. I have a 50 ohm coax transmission line coming out of the electronics housing; right now I'm just modifying the end of that cable into a "coaxial dipole" (design I found on the internet). This is a 1/2 wave section of core, with the corresponding 1/2 wave section of shield folded back down over the feedline, to form a simple dipole.

The coaxial dipole works OK at short ranges (up to a mile or so), but there must be a better way to do this. In fact, based on the stuff I'm reading, it seems that a dipole is a "balanced" antenna, but a coax feed is "unbalanced" ... would I be better off with a whip and small metal ground plane? How would I match this type of antenna to 50 ohms? What sort of instrument would I need in order to check the impedance? Essentially I'm looking for something easy to build without much (if any) tuning required, doesn't need to be high gain.

It will be tough to get the antenna more than a foot (maybe two) out of the water, and the platform will be rolling and bobbing around a lot, so I'm reluctant to use the seawater as a ground plane. Figure the tuning would change too much. I also expect that in general, a low-gain antenna on the remote side will be better - generous vertical beamwidth.

thanks for any suggestions

first the dipole as you describe it is probably not what you think it is. if you fold back 1/2 wave worth of shield you end up with an antenna that is 1 wavelength end to end... this should result in a very high feedpoint impedance and a poor match to your transmitter. the normal way to do this is to fold back 1/4 wave worth of shield thus giving you a 1/2 wave end to end dipole which should have a reasonably low impedance, though not always a great match to 50 ohms it should work better.

for other options... a simple 1/4 wave ground plane is probably the easiest. a 1/4 wave vertical wire with 3 or 4 1/4 wave radials is a reasonable antenna. there are other variations that would be good on 900mhz, one takes the vertical wire and winds it into a small coil then has another 1/4 wave above it so you end up with 2 phased 1/4 wave sections giving a bit more gain at lower angles that should help you. if you can get the ground plane on a 1 to 2' mast out of the water that should help the range quite a bit, especially with waves and bobbing around. another option might be a J-Pole, look that up in the books, it has some small advantages over a 1/4 wave groundplane i think. you can also do a phased coaxial vertical where you have multiple 1/4 wave sections with coax phasing for more gain, but also more complexity to tune.

An underground buried antenna would be an example of a
very low-profile antenna. Virtually invisible antennas
are another example. Disguised antennas (e.g. flagpoles)
are another example. Attic antennas are another example.
In general, low-profile antennas are inferior in performance
to high-profile (extremely visible) antennas.

Some of those "other definitions" might be better described "low
(visual) impact", rather than low profile.

Dave, you're absolutely right, the existing antenna is 1/2 wave end-to-end, not 1/2 wave per section.

As for your other suggestions - based on other reading, it seems like J-Poles are finicky to attach to coax. And I've looked at phased/stacked dipoles, looks promising but I worry about the narrow vertical beampattern.

For an elevated ground plane scenario - what's better? Radials, trimmed to resonant length, bent down 45 degrees or so (I've read since that this is required for 50 ohm impedance) -- or a simple ground plane, 90 degrees to the axis of the 1/4 wave whip, min. 1/2wave diameter? 900MHz is a pretty small wavelength, I'd be fine with using a solid 6.5" ground plane if it would get me better performance than radials.

I`ll risk being the fool. We sometimes test for illumination of a
reflector. We would not be concerned were it not advantageous to do so.

With 180-degree radiation, we fill the dish, using all its surface.
With 0.1-degree illumination, we might as well remove all but the
illuminated area. It would save dead load and wind loading.

My answer: The 180-degree radiation angle will receive a larger area of
the plane-wavefront and extract more watts from the wave with a given
number of watts per square area.

Best regards, Richard Harrison, KB5WZI

a solid ground plane would be more efficient, but is of course bigger,
heavier, and more wind load if you are worried about it blowing around. the
3-4 radials bent down gives an easy way to fine tune the impedance... of
course if they aren't stiff enough they can get bent if slapped around in
waves.

The question you have to ask yourself is, does it intercept all of the energy reflected toward it, or only some fraction of it.

We should always be cognizant of the limits imposed by the absence of a free lunch.

That reminds me of a story that used to circulate about the ham writing a
letter to the insurance company explaining how he incurred his injuries
while working on his antenna tower.
Something about: 300 lbs of tools in a bucket at the top of the tower and
the bucket was on a rope that went through a pully at the top of the tower.
he weighed only 150 lbs
and as he accelerated upward, he forgot to turn loose of the rope
met the bucket with his head half way up (and again with his ankles half way
down because the bottom fell out of the bucket when it hit the ground).

Does anyone have a link to this original story ?

The original is almost certainly lost in the mists of time. My dad used
to tell me a version of that when I was a little kid. And he probably
heard it from his dad.

Mythbusters looked into this myth and ircc they found it not only false
but impossible. I could be wrong though.

Dave WD9BDZ

BTW: Glad to see you back Roy...

Here it is -- it's called sick note!

The Sick Note

Dear Sir, I write this note to you to tell you of my plight
For at the time of writing I am not a pretty sight
My body is all black and blue, my face a deathly gray
And I write this note to say why I am not at work today

Whilst working on the 14th floor some bricks I had to clear
To throw them down from such a height was not a good idea
The foreman wasn't very pleased, the bloody awkward sod
And said I'd have to cart them down the ladders in my hod

Now clearing all those bricks by hand, it was so very slow
So I hoisted up a barrel and secured the rope below
But in my haste to do the job I was to blind to see
That a barrel full of building bricks was heavier than me

And so when I untied the rope the barrel flew like lead
And clinging tightly to the rope I started up instead
I shot up like a rocket till to my dismay I found
That halfway up I met the bloody barrel coming down

The barrel broke my shoulder as toward the ground it sped
And when I reached the top I banged the pully with me head
I hung on tightly, numb with shock from this almighty blow
And the barrel spilled out half the bricks, 14 floors below

Now when those bricks had fallen from the barrel to the floor
I then outweighed the barrel and so started down once more
Still clinging tightly to the rope, my body racked with pain
When halfway down I met the bloody barrel once again

The force of this collision, halfway up the office block
Caused multiple abrasions and a nasty case of shock

Still clinging tightly to the rope, I fell towards the ground
And I landed on the broken bricks the barrel scattered round

I lay there groaning on the ground, I thought I'd passed the worst
But the barrel hit the pulleywheel, and then its bottom burst
A shower of bricks rained down on me, I hadn't got a hope
As I lay there bleeding on the ground, I let go the bloody rope

The barrel was now free to fall and down it came once more
And landed right across me as I lay upon the floor
It broke three ribs and my left arm and I can only say
That I hope you understand why I am not at work today!

Hi, Dan! I did get your second message on Monday, and replied to
it... but a mailer problem on my system ate the outbound mail, alas.

The answer to your question is: yes, by all means go ahead and post
the link to my page about the Laport book. The only change I'd
suggest is purely editorial - there's an extra blank in the
"6-by-9- inch softcover" text which could be removed. Otherwise, it
looks just fine.

Thanks much for being willing to add the link to your antennas page!

Jim Kelley, AC6XG wrote:
"The question you have to ask yourself is, does it intercept all of the energy reflected toward it, or only some fraction of it."

Nothing is perfect as Jim observes. "Imperfections" are sometimes exploited to improve an antenna pattern. To a first approximation though, we assume that all the parallel rays intercepted by a dish are focused on the radiator and aid, adding in-phase. Received carrier power excites the antenna and this causes a minimum of 50% of this power to be re-radiated if the antenna is perfectly matched to to the receiver load. The antenna`s radiation resistance in this case becomes the Thevenin`s source resistance for the receiver load on the antenna. This requires a conjugate match between the antenna and receiver input impedances.

50% of the received power to the receiver is the best that can be done under optimum conditions, that is , with a perfect match. With a 100% mismatch, a short-circuit, 100% of the intercepted power is re-radiated by the antenna. If the antenna is open-circuited, it accepts none of the power focused upon it.

>omnidirectional antenna with no gain?

Hi All,

Well, it is time to discard the speculation and let modeling approach
this for an answer that at least offers more than swag.

First we strip away the sphere and solve this in two dimensions. To
do that we simply construct a ring of sources surrounding the
prospective antennas and let the winning design emerge.

EZNEC+ ver. 4.0

Dipole in Ring of Sources 11/2/2005 10:00:48 PM

--------------- LOAD DATA ---------------

Frequency = 70 MHz

Load 1 Voltage = 4.783 V. at 23.52 deg.
Current = 0.06643 A. at 23.52 deg.
Impedance = 72 + J 0 ohms
Power = 0.3177 watts

Total applied power = 2000 watts

Total load power = 0.3177 watts
Total load loss = 0.001 dB

EZNEC+ ver. 4.0

Vert Yagi in Ring of Sources 11/2/2005 10:21:32 PM

--------------- LOAD DATA ---------------

Frequency = 70 MHz

Load 1 Voltage = 1.418 V. at 25.9 deg.
Current = 0.1182 A. at 25.9 deg.
Impedance = 12 + J 0 ohms
Power = 0.1676 watts

Total applied power = 2000 watts

Total load power = 0.1676 watts
Total load loss = 0.0 dB

As the Bard would offer, there's many a slip between the cup and the lip. For a first pass approximation, and for all the potential for errors (which can now be routed out instead of gummed to death), it appears that the low gain (directivity) dipole absorbs more power than the high gain (directivity) yagi.

Sorry, absolute blx. You are getting confused with a covert antenna.

A low profile antenna is one that is designed not to stick up when
vertically polarised, and may at the same time be not visually
intrusive.

They are most often found (and visible) on the roof of security vans
or buses, and look like a small flat-ish upturned dish - for UK
hi-band (170MHz) being about 18" across and about 2-3" high. In most
applications they are omnidirectional and vertically polarised.
Technically they are a slot antenna - a Google search will explain how
they work. They have the advantage that the metal fixing base will act
as a ground plane so they can be fitted on fibre-glass bodies without
worry. They are popular on buses as they don't get pulled off by the
vehicle wash.

2m antenna?

-Simple!

Cut a piece of wire, 1/4 wave long.

Solder wire to inner lead of the end of a coaxial cable.

Find a stick of wood, plastic or fiberglass, at least 3/4 wl long.

Tape wire and coax to stick.

Fix stick to rucksack, so that the antenna wire is as high as possible.

Connect coax to radio.

That's it!

I'm putting up a tower in the next week or so. It will have a TA33.

I've been putting up antennas for years, but never with a tower. I know the old adage that you should put up as much aluminum as you can afford as high as you can put it. However, will there be a noticeable difference between 34' and 44'? I work DX and with the declining sunspots, I suspect that on some weak signals it might.

Thanks

Easy......

At One Wavelength the "spray" on the antenna opens fully........as you raise the antenna the angle of take off lowers......(getting you to your DX station with more apparent power).

-In W2PV's bible...the take off angle of a 3 element beam at 1 wl is 14 degrees, raise it to 1.5 WL and now the take off is 9 degrees...go to 2 WL and its 7 degrees.

-Now take into consideration the useable angle of propagation, as the angle rises you will begin to use the higher lobes of your antenna.

-There are times that because of the very high propagation angle my vertical is stronger than my 5 ele @ 150' and my 4 element at 106' and my multibander at 68'......

3075. Re: 900MHz antenna at sea surface

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-03 15:59:29 UTC
From: Bob Bob <bob3bob3@cox.net>
Message-ID: <2oop33-r9a.ln1@p400bob.personal.cox.net>
Source record: 68272

Hi Jim

Along with comments from Dave I thought it might be worth mentioning a few more points.

Think of 900MHz as line of sight and any obstruction is an issue to plan for. It is worth keeping the antenna gain low because of wave slap action tilting the structure and radiation pattern. Also consider mounting it as high as you can off the water surface, say a few metres. Hopefully this will allow for the device rolling into a wave trough whilst still giving you reasonable range. The best analogy here is to replace the antenna with a lamp and se how far you can see it from.

If you end up needing high antenna gain consider gimballing the antenna to keep it oriented properly. I'd stick to providing the gain at the ship/shore end though.

If multipath reflections and cancellations are a problem (and honestly I dont think they are in a water/wave environment - more an issue between trees and buildings) then consider a horizontal antenna like a halo, bent dipole or "3 leaf clover". The plus with a horizontal is that the antenna aperture is wide rather than high so phase cancellations are much less of a problem.

You should also consider that what ever data you are sending might be lost periodically so whatever it is make sure there is a forward error correction or retry mechanism where needed.

Cheers Bob VK2YQA

Jim Morash wrote:
"It will be tough to get the antenna more than a foot (maybe two) out of the water."

It may be worth the effort for the sake of your hardware.

Distance to the horizon in miles is the square root of teice the antenna elevation in feet.
Two feet elevation puts the horizon at two miles. 20 feet slevation on the other end of your path extends it by 6 miles. Low obstructions may block a very low path at times as 900 MHz requires a line-of-sight path. You might anchor a buoy to hold your antenna at a convenient height.

A 1/2-wave coaxial dipole works about as well as any VHF or UHF antenna on a boat or float. Commercial versions use 1/4-wave of rigid tubing as a skirt over the coax feedline. This tubing is the lower half of the antenna. The upper half is a 1/4-wave whip mounted on the lower half. There are no radials to get in the way or poke out any eyes.

Best regards, Richard Harrison, KB5WZI

That makes sense. Thanks for the tips.

On page 16-23 of the ARRL Antenna Book, 19th ed, Figure 35B shows a very simple vertical J design. It's open-stub, direct fed from (in fact, pretty much made out of) 50ohm coax, with a 3/4 wave length of core conductor and a parallel 1/4 wave wire coming off the shield. Looks almost too easy... any thoughts on how this would compare to the 1/4 wave whip with ground radials? It's got a larger aperture, but I don't understand how the grounding is meant to work...

Steve - www.ukspeedtraps.co.uk wrote:
> Thanks for that, so a 1/4 wave does not need a counterpoise then?

Strip 1/4WL of insulation from the coax. Fold the outside
braid back along the coax. That will leave you 1/4WL of
center conductor exposed (you can leave the center
insulation in place) and the braid will provide the
other half of the antenna which should be insulated
to avoid backpacking RF burns. Kraus calls such a
"vertical 1/2WL sleeve antenna. On edge it looks like:

```
------------------+
------------------------------+ 1/4WL
==================================================
------------------------------+
------------------+
1/4WL
```

Richard (& Bob),

I didn't think of simply calculating the distance to the horizon...
oops.

The problem is that this is a mobile device that will spend most of its
time underwater. It will not be particularly stable at the free
surface, hence it will be tough to support a tall antenna mast without
it waving around wildly. The taller it is, the more it's going to move
around.

The hostname ("www") can be left off in most cases when contacting the
default web site. Failure to set things up like this on a commercial
site is usually considered an error.

The center of the first lobe's elevation angle can be calculated by:

arcsin of (a/4*H), where a=1 and H = the antenna height in wavelengths.

Plugging in 34 and 44 feet respectively (after normalizing to wavelengths), will show you how much improvement you are likely to see in reducing the takeoff angle.

Keep in mind the TOA is a cone or lobe, not a line.

At 14.1 Mhz, a wavelength is approx 69 feet. So 34/69 is .49. The value of H for 20m and 34 feet is .49. The formula then is arcsin of 1/(4*.49)....this will give you the TOA (takeoff angle) for your horizontal antenna at 34'. Do the same calculation for 44' and you will see the TOA is lower.

Do the calculation for each band you are interested in. Be sure to calculate the wavelength for each band:

982/f, where f is in Megahertz.

BTW, the first null is found by using a=2, the 2nd lobe (if there is one) will be found at a=3, the second null (if there is one) will be found at a=4

You will see these additional lobes and nulls on 10 meters, but not on 20m

Hope this helps. 73

...hasan, N0AN

p.s. Every little bit helps if you are a DX'er.

In that case I do that, and feed it all up the inside of the top element of
a fishing pole I also use for SOTA work with a small beam. I can then seal
it in with aradite.
Thanks again

You might want to look a a 1/2 Wave vertical base loaded antenna
similar to the 1/2 Wave used on sailboat mast tops. Morad makes
one for Vhf. Your real problem will be, when weather causes the
SeaState to be higher than the antenna above the wave troughs.
In this state you range is going to be considerably reduced whenever
the bouy is in a trough. You might just look at designing a
fiberglass antenna mast like 6 Ft long with a counterweight at the
bottom anchorpoint, the electronics package in the middle, and the
antenna at the top, which would give the bouy's antenna 3 Ft elevation
above the SeaState. In a past life, I designed some monitoring bouys
for NOAA, and this is how we solved the antenna problems. Still didn't
solve all the SeaState problems for Heavy Seas, but worked very well
for up to 4 Ft Seas. 900 Mhz isn't exactly the best choice for Maritime
bouys, for just these reasons. You ight also look at the transmission
data protocol, and see if it is compatable with lost packet recovery
techneques, as when the bouy is in moderate to heavy seas, you going
to lose about half the data packets due to SeaState Path losses, which
will seriuously cut into the data thruput your expecting.

This is not a technical term. It is a relative descriptor and can mean many
things. The words simply mean an antenna that is lower than somebody's idea
of a non low-profile or normal antenna.

The meaning of "low" should be obvious; "less than... in some respect.
Usually a physical dimension."
Profile can refer to height or width. Most commonly the height off a
surface. Examples already given accepted.

Finally someone mentinoed the curvature of the sea...

Answers:

The 1/4 wave ground plane with a flat plate or 3-5 radials [drooping or not]; the coaxial "sleeve" dipole and the "J" are all pretty much the same thing / pattern-wise. The "J" and sleeve/coaxial dipole may be easier to get up higher, however.

The sleeve dipole is a 1/2 wave TOTAL, just like a regular dipole and coax feed is standard. The "j" is nothing more than an end fed 1/2 wave (where the 1/2 wave dipole is a center fed half-wave).
These are all fairly simple to make and the "J" shouldn't be a big problem, even with it's much debated so-called feed-line radiation 'problem'. They work just fine.
I think the main issues are:
1- As Richard correctly points out, sea / earth curvature means there is a minimum altitude required for a given receiver distance. With this case of the low "bouy", it will be the larger of determining factors and the other end will require greater altitude to make up for small changes at the "bouy".

2- Sea action means an omni gain antenna is contraindicated (not a good idea) because there will be larger variations in signal strength as it bobs around. This is because this "gain" is obtained by compressing the radiation pattern more toward the horizontal and as the "bouy" rocks, you more quickly get to the points where the signal drops off - above and below the horizontal where the signal peaks. Trying to get a "stable" platform with non active means (perhaps a weighted pendulub under the antenna on a gimble) won't work well due to the accelelrations involved - it may rock more than the "bouy". I would first try a stabilizing "keel" if this is an option, to provide a little stability to the "bouy". Depending on its construction, it may rock moerthan the surface, but be stabilized by being "anchored" to the water below (which win't be moving as much as teh "bouy" can.

Just like in real estate, the three most inportant things in antennas are altitude, altitude altitude...

Hope this helps & good luck

Steve,

I agree that the sleeve dipole, coax-based J, and whip with radials should all have the same radiation pattern, but I get the impression that performance might vary quite a bit (specifically the impedance matching?).

As far as increasing height goes, I agree, the thinner antennas will be easier to raise than the version with radials.

Thanks all for helping me think this through. Now I need to do some testing.

Moving back one half wave:

EZNEC+ ver. 4.0

Vert Yagi in Ring of Sources 11/3/2005 2:37:02 PM

--------------- LOAD DATA ---------------

Frequency = 70 MHz

Load 1 Voltage = 1.655 V. at -135.94 deg.
Current = 0.1379 A. at -135.94 deg.
Impedance = 12 + J 0 ohms
Power = 0.2283 watts

Total applied power = 2000 watts

Total load power = 0.2283 watts
Total load loss = 0.0 dB

moving it such that its "driven" element is dead center to all
radiators (original configuration had the reflector in dead center):

EZNEC+ ver. 4.0

Vert Yagi in Ring of Sources 11/3/2005 2:40:58 PM

--------------- LOAD DATA ---------------

Frequency = 70 MHz

Load 1 Voltage = 1.584 V. at -22.13 deg.
Current = 0.132 A. at -22.13 deg.
Impedance = 12 + J 0 ohms
Power = 0.2091 watts

Total applied power = 2000 watts

Total load power = 0.2091 watts
Total load loss = 0.0 dB

It looks like you'd have to use an array of non-coherent sources in order to get rid of the phase cancellation effects (and really see what's going on).

Thanks Richard.

An antenna one, rather than an antenna +/- source one. Yes.

EZNEC+ ver. 4.0

Dipole in Ring of Rnd Sources 11/3/2005 5:39:03 PM

--------------- LOAD DATA ---------------

Frequency = 70 MHz

Load 1 Voltage = 0.002611 V. at -33.23 deg.
Current = 3.627E-05 A. at -33.23 deg.
Impedance = 72 + J 0 ohms
Power = 9.47E-08 watts

Total applied power = 1364 watts

Total load power = 9.47E-08 watts
Total load loss = 0.0 dB

then moved quarterwave:

EZNEC+ ver. 4.0

Dipole in Ring of Rnd Sources 11/3/2005 5:41:17 PM

--------------- LOAD DATA ---------------

Frequency = 70 MHz

Load 1 Voltage = 0.00676 V. at -110.1 deg.
Current = 9.389E-05 A. at -110.1 deg.
Impedance = 72 + J 0 ohms
Power = 6.348E-07 watts

Total applied power = 1364 watts

Total load power = 6.348E-07 watts
Total load loss = 0.0 dB

then moved backwards a quarterwave

EZNEC+ ver. 4.0

Dipole in Ring of Rnd Sources 11/3/2005 5:44:52 PM

--------------- LOAD DATA ---------------
```

Frequency = 70 MHz

Load 1 Voltage = 0.004604 V. at 29.97 deg.
Current = 6.395E-05 A. at 29.97 deg.
Impedance = 72 + J 0 ohms
Power = 2.944E-07 watts

Total applied power = 1364 watts

Total load power = 2.944E-07 watts
Total load loss = 0.0 dB

EZNEC+ ver. 4.0

Yagi in Ring of Rnd Sources 11/3/2005 5:48:14 PM

--------------- LOAD DATA ---------------

Frequency = 70 MHz

Load 1 Voltage = 0.07004 V. at 66.62 deg.
Current = 0.005837 A. at 66.62 deg.
Impedance = 12 + J 0 ohms
Power = 0.0004088 watts

Total applied power = 1364 watts

Total load power = 0.0004088 watts
Total load loss = 0.0 dB

moved back halfwave:

EZNEC+ ver. 4.0

Yagi in Ring of Rnd Sources 11/3/2005 5:51:43 PM

--------------- LOAD DATA ---------------

Frequency = 70 MHz

Load 1 Voltage = 0.09133 V. at -53.63 deg.
Current = 0.007611 A. at -53.63 deg.
Impedance = 12 + J 0 ohms
Power = 0.0006952 watts

Total applied power = 1364 watts

Total load power = 0.0006952 watts
Total load loss = 0.0 dB

> (and really see what's going on)

Hmmm, at least 1000 times more response... so what's going on? (aside
from a possibly poor implementation of random). Trying to refine the
sources table with tighter random assignments is positively brutal
under EZNEC's primitive (read no) handling of columnar data.

I'm trying to get some info on the Antenna on Pages 25-27 of Sept. 83' QST.

I don't have access to the article & I'm wondering what the dimensions of the antenna are, the feed point/method & the ground plane (if any).

Any help would be appreciated.

3102. Selecting a rotator

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-04 17:25:11 UTC
From: Rod Maupin <gridman@ywave.com>
Message-ID: <11mn6bmit0a6e2d@corp.supernews.com>
Source record: 68149

I have never purchased a rotator before and I have one question.

You look at the specs for a given rotator, and it says that it will handle say up to 10 square feet wind load area. You then look at the antenna specs, and if the Wind Surface Area for it is less than 10 square feet, then you have a match? Is this correct?

Thanks for the help.

A keyword search of the ARRL files turns up a reference but does not
have a link to the article. You might try getting the CD for 1983. The
article will be on it.

That is mostly correct. The rotator sqft rateing is the maximum of the
rotator. The antenna will also have a specification of the sqft rateing.
If you have two or more antennas on teh rotator then you have to add the
sqft of each antenna and come up with less than the rotator rating. The
bigger the differance, the more safety factor you have.
It is not usually a problem but also check for the weight the rotator will
support. Also if the rotator is inside the tower it will handle a bigger
load than if it is mounted to a pipe on top of the tower.

Richard,

It's not clear what aspect of your sources is "Rnd", but the fact that
they are monochromatic is still problematic.

Hi Jim,

You lost me on that curve. Monochromatic. The sources exhibit an
even distribution of varying phase in a random order. That was
tedious to accomplish, but achievable - in a group of 360 possible
degrees of phase, you eventually cover the field. On the other hand,
if you are suggesting that there needs to be an equally random
distribution of frequencies then that has its obvious issues of
practicability. What is the lowest frequency and what is the highest
frequency? That question has all the hallmarks of which infinity is
the biggest?

Anyway, I would surmise that if I could achieve both random phase and
frequency distribution, then the difference between a simple dipole's
response and that of a yagi antenna would be trivial. This would be a
given seeing that the parasitic elements would be virtually invisible,
rendering the "driven" element un-differentiable from the simple
dipole.

i.e. what Roy said. But I think there's still more to it. I tried to
give the other Richard a hint about it but it didn't resonate.

I am considering ordering the MFJ-269 HF/VHF/UHF Antenna/SWR/RF Analyzer.

It sounds like a Swiss Army knife device and I should be able to send a lot of old equipment to Ebay. Does anyone have any comments to make on it? Good or bad?

I have read the review in May 2005 QST and the manual available at their website.

> matching?).

Nope. I disagree. Commercial sleeve-coaxial dipoles are driven w 50 ohm coax, I have one - works great to extend the range of my 5-W 2 Meter hand leld for various temporary Ham communication assisted events. If you are worried about the so called 50 sv 75 ohm mis match.. Believe me, it is nothing.
Ditto for the gnd plane 37 ohm mismatch (identical SWR non issue). The antenna length can even be adjusted to get an improvesd SWR and this may not be where the antenna is purely resistive. This is way, way down the list of worries for your situation.

"J" s are matched to 50 ohms. I don't believe the much discussed feed-line radiation is a significant practical problem.

Something I thought of after clicking last time. Look @ the Arrow antenna version of the "J". It is also much discussed and argued about, but works. I haven't studied it enough to have a well reasoned opinion, but highly suspect it has advantages over the standard "J" that are not only mechanical. He has no 900 MHz version, but it is a rugged construction idea. I want to get one and measure the "bad" external feed line currents (yes, I have Fischer clamp-on RF current probes)
http://www.arrowantennas.com

There's also the "sleeve dipole with the cut shield" referred to previously on this group which looks easy and interesting. .
http://www.ansoft.com/news/articles/04.05_MWJ.pdf

One more thing I just thought of to worry about. Salt spray:
1- Corrosion of the materials used.
2- Geting into critical locations and causing unwanted conduction. I think you mentined a radome, which reminds me...
3- A plastic radome (Pipe or whatever) will require you to SHORTEN the radiating elements a bit or you'll resonate too low in frequency. [[build, insert THEN measure]]

"Swiss Army knife" is a good metaphor. In your pocket, it's always available and handy for that simple job. It's got a saw good for fast, rough cutting, but no competition for a chain saw for speed or a scroll saw for precision. The file will cut metal, but it's not a Swiss file set or a wood rasp either. And so forth. Likewise the MFJ. I use is frequently for a quick measurement, and that's often good enough. But when I really need precision, out comes the GR bridge, network analyzer, and whatever other real tools are required.

Ironically, the thing it does worst, in an urban setting at least, is actually measure antenna impedance. Like any broadband impedance meter, it's dismally bad at that particular job because RF from broadcast and other sources drives it bonkers.

So by all means get one. You'll find you use it a lot. But don't be too quick to unload your other gear.

Well, back in my college days (the first time) I had a phys ed class
called "The techniques of Bait and Fly Casting". We had to be able to
put the "bait" through a 16" tire from the width of the field house (a
bit wider than the width of a basketball court.) to pass.

I haven't used a spinning rod in over 25 years. I'd be lucky to hit
the other side of the field house let alone the hole in the tire.

Hi Jim,

I also approached the problem the same way, this is in glaring
contrast to what I've written in the past two posts which are vastly
divergent from this sense of "equal signals."

As I originally presented data from the model of "equal signals
arriving from all directions" it presented that a dipole's response
was separable from that of a yagi, and showed more response which
contradicts some correspondents, and aligns with others.

Such an outcome stands to reason, the yagi cannot see all sources, the
dipole can. If I illuminated the yagi from each source in turn (all
others off) and correlated the response to the source's angle, the
composite would simply reveal the characteristic yagi response lobe
and the sum of those powers MUST fall below the total power available
to the dipole.

The one over-riding difference between all these scenarios and the
expectations of the yagi is that the yagi is not illuminated with a
plane field, but with a radial field. The composite front of many
sources presents a complex antenna (the yagi) with the appearance of a
wave of extremely high curvature impinging upon it. The mechanics of
gain/directivity are not going to function in the same manner to that
yagi for both fashions of applying the power. Hence the yagi fails to
exhibit a higher response than the simple dipole.

It's ok, but has one known short coming (other than its known and accepted general low/ medium accuracy). It appears to do worse at LOW freqs that the 259. Mine shows about 25% X for a purely resistive 4:1 load (either 200 or 12.5) in the 1-4 Mhz range. A post here not to long ago reported that the QST review showed the same thing.

you can't expect lab accuracy for $300...

Let me thank you again for the work you've put in on this. The thing is, the idea of squeezing a dipole field pattern into the shape of a Yagi pattern for example, pretty much dictates that with the proper field geometry, we should be able to realize equal amounts of energy in both antennas. I think that's the correct answer. I'm just trying to see a way to get to it. Another approach might be to integrate the results from a large number of point sources.

Thanks for the quick reply.
The "old equipment" I am referring to is pretty primitive and quite
old.
The only really good pice of equipment I wonder about replacing is an
Heathkit IM-4190 directional coupler for 100-1000 mhz. It was not
available for long and it has served me well on 144 & 440 mhz.

Impedance matching isn't much of a problem with any of those antennas. The main issue is feedline decoupling. Current will end up on the outside of the feedline unless, of course, your antenna is mounted directly on a metal structure -- in which case the current will end up on the outside of the metal structure. This current radiates just like the current in the antenna, and this added radiation can cause a number of problems. One is that it can modify the pattern and reduce the radiation toward the horizon. Another is that the current can get back into the transmitter and other circuitry where it doesn't belong. Finally, it can effect a change in feedpoint impedance, since the coax is part of the antenna you probably didn't account for.

The current can originate by two mechanisms, conducted and coupled. http://eznec.com/Amateur/Articles/Baluns.pdf explains the conducted mechanism. Current can be coupled from the antenna to the feedline even if you're using a solid ground plane of moderate diameter, and all the popular implementations have coupled current to some extent. If you search for a while, you'll find people both raving about and raving at J-Poles. I suspect this is at least partially due to the amount and phase of coupled current they ended up with due to their particular installation. The amount of coupled current depends on the length and path of the feedline, as well as the path to ground or some large body. If I were designing the antenna you describe, I'd use a "current balun" (common mode choke -- see the balun article) at the feedpoint and about a quarter wavelength down the line. At that frequency, a good size ferrite core or two of the right type might provide adequate impedance.

Half wave antennas have relatively little conducted current because the feedpoint impedance is so high. But feedline current can still exist due to coupling.

Yet if you provide the same power to the dipole and the Yagi and integrate the total field from each, the total field powers from both are the same.

So is reciprocity invalid?

Yes, it works fine. Not a precision piece of test equipment but also does not carry the price tag. Like everything else in life it is a trade off, great price with reasonable response. All in all it is still one of the best pieces of equipment I have bought for amateur radio work and I would not be without it.

Hi Roy,

No, the presumption:
that this specific problem supports that reciprocity
is invalid.

Feel free to exhibit that the sum of powers, from identical remote
sources, located in a locus of points equidistant from a given point,
applied to
1. a dipole;
2. a yagi
demonstrate identically recovered power.

This is not the same as applying the same power to both and
integrating at a locus of points equidistant from a given point.

I could, of course, be wrong. I will investigate further if you have
any constructive suggestions such as Jim offered. I think it would be
instructive to be able to confirm it through available tools.

>
> Total load power = 0.3177 watts

Taking the determination above as the "standard" I then have
progressed to place an NBS yagi in three space about the center to
obtain its best result.

All such expressions (x,y,z) of the placement of the NBS yagi are with
respect to its "driven" element.

0,0,0 Power = 0.2091 watts
.5,0,0 Power = 0.2198 watts

1,0,0 Power = 0.1429 watts
1.5,0,0 Power = 0.1026 watts
2,0,0 Power = 0.1601 watts
2.5,0,0 Power = 0.2113 watts
3,0,0 Power = 0.1571 watts
3.5,0,0 Power = 0.06028 watts
4,0,0 Power = 0.04128 watts

So, within one quadrant, and over the space of roughly a wavelength, and at intervals of roughly one eighth wavelength, nothing emerges as being equal to the "standard" above. Except perhaps a hidden peak between 0,0,0 and .5,0,0. To investigate this:
.25,0,0 Power = 0.2286 watts
examining further:
.125,0,0 Power = 0.2219 watts
nope, examining further:
.375,0,0 Power = 0.2278 watts
nope, examining further:
.30,0,0 Power = 0.2291 watts
nope, examining further:
.35,0,0 Power = 0.2285 watts
nope, looks like the one before at .30,0,0 is the new sweet spot.

Now, to proceed to investigate the other quadrants to see if there is symmetry:
-3.5,0,0 Power = 0.03997 watts
0,3.5,0 Power = 0.005925 watts
0,-3.5,0 Power = 0.005859 watts

This last offers that on the Y axis there is a strong symmetry, and along the X axis there is a moderate symmetry. Now, in regard to both the X and the Y axis, there is a moderate symmetry. If we were to look at the fine data attempting to find the peak, we should notice that the "center" of the antenna lies between the "driven" element and its reflector. My having chosen the "driven" element as the nominal center was in error and my guess is that if I re-visited the same quadrant test above, with that new center at the sweet spot, then we would find very strong symmetry in all four quadrants. I will add that the Y axis data supports this due to its strong symmetry that is relatively immune from the choice of antenna center - at least at this scale.

Putting that aside, it is enough to suggest that barring an exquisitely positioned peak of rather a sharp rise, then the yagi exhibits a poorer response compared to a dipole of approx. 1.4dB.

Others are encouraged to investigate further to reclaim that missing dB or to put the horns to my error.

Source record: 68026

Dear friends:

Reciprocity principle it is not violated in this situation but... which are the antennas?,

Let us feed a directional antenna that emits a hypothetical conical beam = 1 sr, pointed toward north pole of the inner surface of the sphere, for example. The radiant intensity or radiometric flow for unit of solid angle in the area illuminated by the antenna, will be 1 W/sr, ok?.

If that same portion of the imaginary sphere receive from outer space, an energy convergent flow on the same previously illuminated area for the beam with a density = 1 W/sr, naturally the directional antenna would be able to pick up it entirely, the principle of reciprocity is respected (not violated?)

Now we make the same thing with a isotropic radiator (same power = 1 W).
The energy density that crosses the sphere's surface going out, now is 1 W / (4*pi) sr, ok?.

If for that surface, comes from the outer side, energy with that same density and we pick up it with the same isotropic antenna we obtain one watt, truth again? (and the principle of reciprocity would be ok)

Now let us suppose that same energy density 1/(4*Pi) W, received from the whole surface of the sphere.

Let us reinstall the directional antenna instead of the isotropìc one.

How much energy it will be able to pick up 1 watt? or 1 / 4*Pi watt?

(could 1 W be picked up if the directive antenna only "see" an sphere's area corresponding to 1 sr?)

Perhaps, the problem would not be on the reciprocity principle but in the way of applying it to this example.

If instead of outlining the problem with antennas and radio signals, the friend had outlined it with another energy form, luminous, for example, and instead of antennas it had proposed light reflectors, would the answers be the same ones?

I believe that it is legítimate (rightfull?) to associate this problem with related phenomenon of radiant energy flow in general.

I also believe that the analogy between directional antennas and a luminous reflectors it is applicable, otherwise we would be to a step of violating the conservation of the energy principle... :>)

Puf...!, I hope I`ll be able to translate this...

73's of Miguel Ghezzi (LU 6ETJ)

El principio de reciprocidad se cumple en esta situación pero... ¿cuales son las antenas?,

Alimentemos una antena direccional que emita un haz conico hipotetico de 1 sr, apuntada hacia el polo norte de la superficie interior de la esfera, por ejemplo. La intensidad radiante o flujo radiometrico por unidad de ángulo solido en la zona iluminada por la antena, sera 1 W/sr, ok?.

Si esa misma porcion de la esfera imaginaria recibiera desde exterior un flujo de energia convergente sobre la misma area anteriormente iluminada por el haz con una densidad = 1 W/sr, naturalmente la antena direccional seria capaz de recogerla integramente, el principio de reciprocidad se cumple...

Ahora hacemos lo mismo con un radiador isotropico (la misma potencia, 1 W).
La densidad de energia que atraviesa la superficie interior de la esfera ahora es 1 W/(4*pi) sr, ok?. Si por esa superficie pasara, procedente del exterior, energía con esa misma densidad y la recogieramos con la misma antena isotropica volveriamos a obtener un watt ¿verdad? (y el principio de reciprocidad continuaria cumpliendose...)

Supongamos ahora esa misma densidad de energía 1/(4*Pi) W, recibida desde fuera por toda la superficie de la esfera.

Reinstalemos la antena direccional en lugar de la isotrópica,

Cuanta es la energía podra ella recoger 1 watt? or 1/ 4*Pi watt?

(¿acaso podria recoger 1 W si solo "puede ver" una zona de la esfera de 1 sr?)

Tal vez, el problema no estaria en el principio de reciprocidad sino en la manera de aplicarlo a este ejemplo.

Si en vez de plantear el problema con antenas y señales de radio, el amigo lo hubiera planteado con otra forma de energia, luminosa, por ejemplo, y en vez de antenas hubiera propuesto reflectores de luz, las respuestas serian las mismas?

Yo creo que es legitimo asociar este problema con los fénómenos relacionados con el flujo de energía radiante en general.

Tambien creo que la analogia entre una antena direccional y un reflector es aplicable, de lo contrario estariamos a un paso de violar

el principio de conservación de la energía... :>)

Puf...! espero poder traducir esto bien...

73's de Miguel Ghezzi (LU 6ETJ)

Why is it that I can received WCBS @ 880kc fairly well at night but WABC @ 770kc suffers from phase distortion like you wouldn't believe! (I'm about 175 miles from both transmitters.) They are both 50 kwatt stations. And why is it that both WBZ (Boston), WBT (Charlotte, NC), WJR (Detroit) and WBBM (Chicago) come in better than either of the New York City stations?

My main complaint is if you punch buttons in the wrong sequence to
activate its 440 mhz capability, you can blow a diode, or so I've read
in the eHam reports. I haven't done it yet, but the it apparently can
happen. The capabilities on 440 mhz are quite limited, compared to
other frequencies, so you may want to consider the 259, unless you
need to measure swr on 440.

Different frequencies, different directions, different sun angles
(even when below the horizon), different ionospheric layer heights,
different skip distances, different ground-path terrains and therefore
different ground-path loss.

I havn`t looked up the directional patterns of the two stations and don`t know your location. If you should happen to be at the edge of a null in the nighttime directional pattern of WABC, that would likely cause distorted fading. WABC may be clear-channel non-directional day and night for all I know. Not many of these remain in the U.S.A. now.

At 175 miles from both transmitters, you suffer interference between the ground wave and sky wave from either transmitter at night, at least occasionally. You probably have solid daytime reception from both stations, but at night, the signal may be stronger, though variable. The sky wave is susceptable to variations in the reflecting layers of the ionosphere at night. These are a function of frequency, reflecting carrier and sidebands differently at times. This can produce overmodulation at times in the received signal. Another factor is likely other stations on the same or adjacent channels which may fade in and out and cause variation from your automatic volume control action even when the interfering stations can not be readily identified. An Adcock, loop, or other directional antenna may produce a big improvement in reception of the desired signal.

Finally, WABC is owned by the Walt Disney company. Maybe you should expect Mickey Mouse performance.

Best regards, Richard Harrison, KB5WZI

There are undoubtedly official sources from the FCC, etc.

The best hand-held guide I could recommend would be the National Radio Club's "Night Pattern Book," a fantastic resource for MW DXers and broadcast listeners. Basically it is a book of maps of North America for each domestic broadcast frequency, with dots representing transmitting locations, and the night time radiation pattern around each.

It's available from the following link:

http://www.nrcdxas.org/catalog/books/

The 5th edition is sold out, but the new 2005-06 edition is scheduled to be out soon.

==========
Dave,

http://www.nrcdxas.org/catalog/books/
Sounds exactly what you are looking for but may take some time to
obtain.

In the meantime, the basic groundwave radiation patterns of mediumwave
broadcast antennas are either simple circles with the antenna at their

centres, or heart-shaped with the antenna at the null.

The first occurs when the antenna is a single vertical mast located near the centre of a large populated area.

The second occurs when the antenna consists of a pair of masts, which radiate a very broad heart-shaped beam, located on one side of the populated area to be covered.

Contour Maps of actual measured field strengths are useful when the basic groundwave patterns are distorted by the terrain, e.g., the existence of mountains, forests, rivers, built-up areas, high-rise cities, or seas, lakes or coastal regions.

Radio frequency Field Strengths are usually measured in terms of "millivolts per meter" or in decibels relative to one volt per meter.

Jim, I've read through the responses you have had and allow me to inject some real world additions. You see I work for the Navy and we have built things a lot like what you are talking about and getting the antenna some height above the water is a requirement. It's actually rather easy to do. A simple fiberglass mast will do it, counter balancing the added weight is easy, since there needs to be enough mass below the surface to balance some sea state conditions

Here is a link to the Newport tracking system http://www.npt.nuwc.navy.mil/autec/barts01.htm This isn't the one we did, but if shows you some ideas

The system people I work with developed, use a different buoy system but works almost the same.

I did some experiments with antennas (900MHz) just as sea level (OK 3 feet above) and could still get a solid connection at about 1 mile, when I raised them to 6 ft I got a solid connection at 5 miles.

Other considerations.. the antenna mast whips a lot and makes recovery (in rough water) a little interesting. There is going to be a switch from the simple ground-plane antenna to a disc-cone due to the danger the ground radials pose.

We also found that putting a LED based flasher on the bouy a real good idea (to see it in low light conditions)

Why not just use the rod and reel? Admittedly some can throw farther
than they can cast.

I doubt there are very many people who can either throw, or cast a
line, at 70 feet, over a particular branch of a rather densely packed
conifer tree. I can do it, however, with a slingshot. A bow or
crossbow would be even better, I'll admit.

Which is why I recommend using my described method, as you can "sight"
up your target. Easy really.

Dave P. wrote:
"Is there any place I can find polar graphs of commercial broadcast stations?"

I have an old book, "Map Book, 540 kc to 1600 kc" published by "Cleveland Insritute of Radio Electronics". In it, WABC is 50 KW non-directional day and night. It shares 770 kc with KOB Albuquerque, 50 KW day and 25 KW night. Also, KUOM Minneapolis and WCAL Nortjhfield are both 5 KW and share the frequency on some schedule between themselves. WNEW St. Louis is on the frequency daytimes only, as is KWA Seattle, 1 KW. XEHB in San Francisco de Oro, Mexico is a 500 watt daytimer on the frequency, as are XELM, 150 watts at Lagos de Morens and XEDI at Queretaro, 1 KW. There is also CMDC, 1 KW at night when it could trouble you in Holquin, Cuba. So, at night there is possible same-channel interderence from New Mexico and Cuba. On 760 kc, you have WJR in Detroit 50 KW non-directional at night and on 780 kc, you have WBBM in Chicago 50 KW nondirectional at night. These non-directional 50KW adjacent channel stations may exercise your AVC.

On 880 kc, WCBS has no same-channel night rivals but WLS (World`s Largest Store, Sears in Chicago) on 890 kc, onetime home of "The National Barn Dance", could work your AVC. Also, WWL in New Orleans occupies 870 kc with 50 KW.
Good preselection will rid you of adjacent channel interference. I lived in Portugal for years and listened to WCBS nightly. I would rock my tuning from 880 to 870 for WWL during fades for my version of frequency diversity. Both stations carried the same CBS programs. My antenna was a Beverage aimed at New York. The receiver was a Hammarlund SP-600 which had plenty of preselection to avoid adjacent channels. Ed Murrow came in very well.

Best regards, Richard Harrison, KB5WZI

hi

i might have a chance to put up a real antenna on my roof and ponder
which type is best"" as i can only do one

my choices are either a multi ele beam or a verticle

looking for what is 'best' overall for all type not just dx

I operate all modes and all bands 160-10

my roof is about 150' off the ground my antenna would be about 30ft off
the roof flat surface

i was realizing that no one antenna is 'perfect' but wondered
generically which would be best overall if you could only get one?

thanks

You guys sure know how to enjoy yourselves trying to analyse
hypothetical situations.

Without any loss in precision, just imagine an isotropic receiver
surrounded by 6 equal intensity beams focussed upon it. Forget all
about an infinite number of radiators.

Or, better still, forget all about the original exceedingly
ill-defined question by a leg-puller. You have been trolled. You
should be ashamed of yourselves for being taken in by such a question.

By the way, the subject of "antenna gains" is amongst the most
confusing of all old-wives' tales. It's worse than so-called VSWR
measurements on non-existent transmission lines. Or from which ends,
or the middle bit, of a dipole does the radiation occur.

Reg.

The best, all round, antenna is undoubtably an approx quarter-wave vertical antenna, or an Inverted-L, on the lowest frequency of interest, with a modest set of a few buried ground radials. An antenna tuner is needed for higher frequencies..

The next best. almost as good, is an approx half-wave dipole at the lowest frequency of interest, fed with openwire line, where no ground system is needed. An antenna tuner is still needed for higher frequencies.

Reg.

D4 works well, but you don't necessarily need to add software, some
operating systems support sntp natively... eg Win 2K and XP. You just
have to work out how to activate it.

Doesn't everyone syncronise their computer clock nowadays?

WBZ in Boston is a clear channel station. I don't think they
have any pattern restrictions; they run 50kw 24/7.

I really like my Cushcraft A3S with the 40 meter option.
However, it does not cover the "new bands" or 80/160. If you were to
mount it 20 feet or more above the roof it would probably work well. I
am in the throws of trying to figure out what to do about 80 & 160
myself. Any way you do it you will have to trade physical size for
band width.

Now would be a good time to start considering what you are going to do
about lightning protection though.

Cec, with the verticals and inverted-L's and dipoles I have ever erected, I have never noticed much difference between one direction and another except when my house or the neighbour's house got in the way. And most of the difference was just my imagination.

Simple antennas, in the average amateur's environment, are effectively omni-directional in all planes without any nulls. I have never had any silly objections to radiation from the feedline, although I have never been certain that I ever had any.

If I ever made made any propagation calculations I always treated my antennas as being isotropes. When the calculating uncertainty is plus or minus 10 dB who cares anyway? I am the last person to suffer from delusions of accuracy. Yet I am a firm believer in Kelvin.

I once made a balun. It was in the feedline for 24 hours. It didn't make a scrap of difference to anything except weight. I still have it. The workmanship and neatness of the windings around the ferrite ring was too good to throw away.

I've just noticed this message is in terms of a history. I am 80 this month.

Reg, G4FGQ.

I must be the only one still using Windows 2000 Pro at my home. It
works well, so I'm in no hurry to "upgrade" to anything else.

But HOW do you make W2K support sntp? I've never found that option, and
I use an external program to make it work.

Thanks,
Earl

You configure and start the Time32 service. These articles should be
helpful:

http://support.microsoft.com/support/kb/articles/Q246/1/45.ASP

http://msdn.microsoft.com/library/default.asp?url=/library/en-us/dnw2kmag01/html/TimeWin2K
.asp

http://support.microsoft.com/kb/223184/

If after you have done the net time /setsntp thing and started the
service and it still doesn't work, it is because some registry
settings are not correct. I have a .reg file with them in, but not
with me. See the second article. IIRC XP is just as unornery.

For sntp servers, have a browse to pool.ntp.org.

Owen

Reg:

I'm afraid you're way behind the practice on this one. In the US, there are many 4, 5 and 6 tower arrays providing as many nulls to protect co-channel stations. The UK got off easy with nationalized broadcasting, where the frequency and location was dictated by the government, and none of that nasty capitalism interfered. Here, the commercial interests are still fighting it out. Check and see if the KLIF website shows their pattern from a linear array of 5 towers just outside Dallas.

I wouldn't have voted for them, but my friend, Geoff KC0FXY, did take a nice shot. And I guess QRZ thought so too.

https://secure.qrz.com/store/qrz_cd.html

So my 6 meter beams are on the 2005-2006 cover.

To explain the shot, the lower beam is a fixed 3 element which is meant to cover the Minneapolis/St Paul metro area.

The 4 over 4 above it is rotarable.

happy birthday if you were around nyc i'd buy you a cake

so if i understood your below, your saying you had a dipole in some
direction lets say n s and your average signals came in same as your
E W dipole?

or say if i had a nice multielement optibeam on 20m and i heard a week
signal started to turn the beam all around findng max signal East

if i switched to my verticle you'd hypothise it'd come in about the same

further if your below was true then wouldn't turning the beam mean my
signal would always be about the same?

or was it just a dipole vs verticle comparison that i spazed out on ?

My rotatable 33 ft. dipole at 50 ft. is a pretty simple antenna, Reg.
It is not omni-directional. Rotating it can make about two S-units
difference on 20m and up to about 4 S-units difference on 10m.

==========

Cec, in the broad expanses of Texas no doubt it has a similar
performance at all other frequencies too. But I suggest a 33-feet
rotatable dipole does not make you an average amateur.

Thanks for birthday greetings all the way from Texas. The World sure
is getting to be a small place! The Internet appears to have shrunk
it more than radio ever did.

Yours, Reg, G4FGQ

Point is that if it wasn't rotatable, it would make me average,
and I would be missing out.

Keep in mind that the 10 sq. foot rating is for a mast with a thrust
bearing, or for an antenna installed a few inches above the rotor. Put a 10
foot mast on top of the rotor (w/o thrust bearing), and the rating becomes
something like 1 - 2 sq. ft. Check out the Yaesu rotors. At the 10 sq. ft.
level, the price is not much more than 1/2 that of the Hygain.

My own opinion, I do not like Oak trees for antenna work.... when the leaves are on, they are difficult, to say the least. However, with winter here, I'm sure you will be able to configure the apex of your inverted V OK in that big tree.

Have you actually considered the amount of real estate you need for an Invertet V for 75M ? With a center height of only 40 feet, your 1/4 wave legs will extend out barely over about 47 feet each side of center. You may be able to do what you are thinking with a simple center mast instead of using the Oak tree. It certainly would make working on your antenna and changing things a bit easier.

Good luck, either case.

Ed K7AAT

in Oregon, too.

You need only the length of line necessary to make from you rig/tuner
to the antenna. The are some cases that the line length may result
difficulty matching. If so, just add a few feet. Don't worry about
resonance.

Tam,

I see what you mean. I was leaning towards the Yaesu G-450A rotator instead of the Hy-Gain AR-40. I read a less than favorable review on that one. However, I also read some unfavorable reviews on the Yaesu G-450A. People's main complaint was about the buttons on the control box not being very good.

Actually, the VHF/UHF antenna I was thinking of putting up is only 1 sq.ft., I was just using 10 sq.ft. as an example. I did read about the thrust bearing and agree with you on that.

Just put up a 140' dipole with 450 ohm ladderline feed.

I'm using an unbalanced tuner with a Spi-Ro 1:1 balun on the output side of the tuner. The balun is one of those designed to be used right at the center feed point of the antenna, with coax as the feedline. I think it should work out fine being directly at the output of the tuner, with ladderline going up to the antenna.

However, there is some disconnect between the rig and antenna. I suspect my balun may be bad internally. What's a good quick and dirty check with an ohmeter (don't know if these baluns are current or voltage types, so maybe include a checkout procedure for both kinds).

I'm just starting to fault isolate. Since the balun is a new link in the chain from rig to antenna, it's my first suspect.

The probably make things with less quality now than they did about 40 years ago. I had an 11 element 2 meter CC beam (please no comments about that antenna) on a AR 33 that was even less heavy duty than the ar40 was at that time. The rotator has been turning a big TV antenna for the last 30 years. For a small vhf antenna I would look around for a used (doubt you could find a new) Alliance U-100. It should be about $ 150 or more less than the ar40. I have one mounted in a tower (no thrust bearing) but the mast goes through 2 plates about 2 feet apart and the hole in them is only about 1/2 inches bigger than the mast and it has been turning a 8 element 14 foot boom 2 meter , 22 element 440 and an 8 element 10 foot boom 220 mhz antenna for about 10 years.

3192. What Would You Do??

With a current balun, you should have continuity from the feedline conductors to the antenna conductors just as though the balun were a couple of pieces of wire connecting the feedline directly to the antenna. There shouldn't be any continuity from one side of the antenna or feedline to the other.

A correctly operating voltage balun will show continuity between any pair of conductors, input to input, output to output, or input to output, just as though they were all shorted together inside. If there's an internal short where it shouldn't be, you won't be able to determine it with an ohmmeter. But you'd be able to see an open connection.

You won't be able to tell a short-circuited current balun from a normally operating voltage balun with an ohmmeter, either.

Using the balun as you are might cause its destruction. If the impedance seen at the input of the ladderline is very high (which is particularly possible if you're using the dipole on multiple bands), the voltage appearing across the balun might well be more than it's designed to handle. There are also likely to be common mode impedances on some bands that will be too high for the balun to be effective. Moving the balun to the antenna will change the bands where those conditions exist, but won't necessarily alleviate them -- assuming you're using the dipole on multiple bands, that is. You might consider taking a look at Cecil's web site for some alternatives.

At 1 square foot, you could save a lot of money and use a TV rotator. I have a G&C on the UHF TV antenna. The same, or similar rotors are sold as ECG, Radio Shack, and ChannelMaster. I think I paid $59 for it from Warren Electronics. It does not seem to have the synchronization problem of the old CD things that went cluck-clunk. My ham rotor is a Yaesu G1000, but it has 3 antennas on top of it, with a HyGain tribander the bottom most. I think the AR40 started life as the CD22 TV rotator; looks like it has an updated control box, though.

Here is the situation: have an inverted V for 80m and noise level is S9.. Not good really....
I did the next logical step and tryied magnetic loop for 80, reciving only, indoors. That antenna failed awfully.... Noise was S8 but I could not hear stations that were 9+10 on inverted V. Did'nt matter how I tryied to rotate the loop, all there was is noise. So, indoors is right out..
All that is left is roof. And that makes my situation interesting. It is a big house with new metal roof, electrically bounded. 10X60 metres, 17 metres hight, angled about 20 degrees. Big ground plane indeed. All I could figure is to get some sort of antenna to the roof so the roof would act as a shield from all the noise generated inside the house. That antenna would be for receiving 80m, can be narrow band (50KHz ok). NVIS pattern would be prefered.
So, I have huge ground plane, lots and lots of noise below it, and need a receiving-only antenna.
What would you do in this situation? Loop, magnetic loop, dipole, short beverage perhaps???
Any advice is welcome. Right now I cant even figure if that roof is acting like a shield or a big noise-sucking antenna..

Andrus

I use 2 ham stick mobile antennas phased to produce a receive antenna on 80m
that works very well.
It has a response that is close to a reasonable sized beverage. They are
spaced 1/8 wavelength apart and feed 135 deg. out of phase with a coax
phasing line. I have a relay setup that lets me change the direction, in my
case north-east / south-west. The signal levels are down from the dipole I
use for transmit but the signal to noise level are much better. A signal
that would be S-9 with S-8 of noise on my dipole becomes S-6 to S-7 on the
verticals with no noise. It makes DXing on 80m fun. Details for the design
of the phasing system are in ON4UN's book on low band dxing. One of the
advantages of using mobile antennas is the mutual coupling is very low
between them. This greatly simplifies the setup. Note that this would be a
poor transmitting antenna do to the poor ground plane I have and mobile
whips are not a good antenna on 80m.

Here is a bit I ran across the other day...

I copied this out of the MFJ-269 antenna analyzer manual:
"Resonance at the feedpoint only repeats when a mismatched feedline is
an exact multiple of 1/4 wl. If the line is not an exact multiple of
1/4 wl, the resonant frequency of the antenna might be shifted higher
or lower by the transmission line. A mismatched line that is not an
exact multiple of a quarter-wavelength adds reactance that can either
cancel antenna reactance at frequencies where the antenna is not
resonant, or add reactance at frequencies where the antenna is
resonant."

My deduction:

In essence, if the feedline is matched there is no problem. If it is a
multiple of 1/4 wave in length there is still no problem! Trying to do
both is a good idea.

Andrus wrote:
"Any advice is welcome."

Andrus has a bonded metal roof 10x60 mtr which is 17 mtr high.

An automobile contains radio noise within its engine compartment by using a metal cover. A roof does not completely cover and surround noise sources within a house, but if it is effectively grounded at the receiving frequency, the roof can help block transmission of noise into an antenna mounted above it.

A dipole is balanced and slightly directional. This helps avoid noise pick up. A balun at the antenna feedpoint helps keep the antenna balanced and allows connection of coax to run through noisy areas without pickup.

A low dipole over a reflective surface has a high-angle radiation pattern, excellent for NVIS.

With an agile antenna tuner you may be able to hear and work stations within several hundred miles.

Best regards, Richard Harrison, KB5WZI

I would go with a simple 'Loop Skywire' in the vertical plane. A
200x100 foot loop is well over a full-wave at 160M so with a balanced
matching device it will be an all-band antenna. I have a 500 foot
horizontal loop that provides absolutely amazing performance so I may
be a little biased <g>.

I would also consider a four bay 40M or a ten bay 20M Sterba curtain.
A bobtail curtain is another possibility.

If you can somehow get your inverted-V to a horizontal position
for testing, you might be plesantly surprised. At my QTH, going
from an inverted-V to a horizontal dipole at the same center
height lowered my noise level by 2 S-units on 40m.

Your deduction is not 100% valid. 1/4WL can be a BIG problem and
worst case for matching.

I guess MFJ is technically correct but confusing. For instance,
assume a 50 ohm antenna and 1/4WL of 600 ohm open-wire line. The
"resonant" impedance seen looking into the feedline would be 7200
ohms, outside the matching range for a lot of MFJ tuners. Half a
century ago, we called that the "anti-resonant" point (akin to a
parallel resonant impedance). Most amateur radio operators should
substitute 1/2WL for 1/4WL in the above MFJ manual quote to avoid
thinking 1/4WL is "no problem".

A couple of antennas that work well at this qth...typical urban environment
with elevated power lines and assorted other racket.
Run a big horizontal loop around the place..feed with coax for recieve only
or twin lead plus transmatch for recieve/transmit. This is the one I am
currently using.
Previous antenna...which also works pretty good was a 100 ft bowtie doublet.
I used to run the doublet with vertical drops on the ends, but found that
any vertical drop on the ends of the antenna really picked up the racket. If
I left the vertical drops off the ends, I never did like the way the Johnson
Matchbox was coupling with the feedline...450 ohm...on 80 meters. I would up
with 10 ft end drops, then running a wire from the bottom of the end drops
back up to the feed point.
Tuned a lot better, broad banded and rejected noise pretty well.

I am considering buying or building a flagpole antenna. My preference is for an antenna that covers 10 to 80 meters. I have seen the one listed at the Force-12 site but would like some independent input on this antenna before buying. Also, I was looking for plans on building one myself but not much luck yet in finding any.

Thanks
Mike

Same as at my QTH. Anything vertical is noisier on receive.

> If I left the vertical drops off the ends, I never did like the way the Johnson
> Matchbox was coupling with the feedline...450 ohm...on 80 meters.

Because your feedline length was somewhere in the ballpark
of 1/4 wavelength and presented a very high impedance to
the Matchbox. Ladder-line feedline lengths for low-impedance
antennas need so be close to multiples of 1/2 wavelength,
a little over 100 feet on 80m. Unfortunately, a lot of
ladder-line-fed 80m dipoles and loops are closer to 1/4WL,
around 60 feet or so which may be worst case for limited range
tuners like Johnson Matchboxes and internal autotuners.

I had one at my QTH but it was so noisey I took it down. Your
QTH might have a lower vertically-polarized noise level so
here is what I did - not exactly a flagpole but may give you
an idea.

I erected a 20 foot long vertical fed at the base with an
SGC-230 autotuner. It had 8 33 foot buried radials. 20 feet
is 5/8WL on 10m. This antenna worked well for transmitting
on 40m-10m. If it hadn't been so noisey on receive, I would
have added a high-Q base-loading coil for 75m operation
although the SGC-230 actually loaded well on 75m. I should
have left it up and switched to my dipole for receive.

A flagpole antenna article at URL:
http://www.sgcworld.com/23ftflagpoleinstall.html
Uses a SGC tuner

Be careful of using PVC pipe -- smaller diameters bend very easy.

Also when using PVC, check the PVC grade for carbon content -- some have enough carbon to upset the resonance points. Had a friend put a commercial vertical in PVC pipe but the carbon in the PVC pipe detuned it and it wouldn't work.

Building a single band flagpole vertical is easy. But making it cover 80 thru 10M can be complex. You probably want to use a tuner of some kind

My 2 cents

Got a Radio Works choke balun I'd like to use for feeding ladderline out of an unbalanced tuner.

The balun has coax fittings on each end.

Ladderline doesn't adapt well to coax interfaces.

What's the best way to put ladderline to my balun coax fitting?

I can kluge a PL-259 plug onto the ladderline.

I guess I could also stick one side of the ladderline in the center hole of the chassis coac fitting, and clamp the other side to the threaded part of the chassis fitting.

Ideas solicited.

Hi Andrus,

Put 1:1 BalUn at end of Coax transmission line as choke. This will
isolate local noise from line input. Also, does your transceiver
share a circuit (identified at the breaker) with a noisy appliance?
Change circuits (go to another outlet that is on a different breaker).
Do you have a good RF ground? This goes against much of the common
lore of dipoles being independent of ground. True, the antenna alone
requires no ground, but somewhere your rig is connected to it, and it
can be a very poor connection to a very poor RF ground. This is a
very common path for noise to enter your receiver.

David, can you please elaborate on how this can be done? And how it can be implemented so that the proper signal activates the unit.

I'm sort of a newbie in this field and would appreciate it if you could explain how this can be done in greater detail.

Thanks again.

Reg, G4FGQ wrote:
"What proportions of U.S. broadcasting stations have antennas consisting of more than two towers?"

I don`t know but from my own experience, the number is large. A new applicant for a station must show he will not interfere with existing stations by limiting his radiation in the directions of the existing stations while providing minimum field intensity, 0.5 to 50 mV, depending on population, in the new service area. A two-tower array cannot satisfy some complicated pattern requirements.

Most broadcasters want to provide more than 1 KW radiation in their areas. Well over one hundred channels in the medium wave broadcast band in North America allow that. There are well over 1000 regional medium wave broadcasters in North America. It is difficult to fit a new broadcaster in when he wants to use real power.

Best regards, Richard Harrison, KB5WZI

I'm sure others here will correct me if I'm wrong, but I believe that what you want to do is a very bad idea. Baluns are not meant to operate under the potential very high SWR conditions you are likely to have on the output of your tuner. Damage to the balun is likely. Besides, what is the point of a balun on your tuner's output if you are using ladderline, anyway?

Hi Richard,

I think what you're seeing is the 3-D interference pattern generated by your sources. I'm not sure that really tells us very much about the antennas themselves. You'd need to surround each of the antennas with a uniform field in order to compare them. By uniform, I mean the field intensity toward the antenna is the same in any direction.

Thanks, AC6XG

Why are you using a choke at that point in the system? You should use either a 1:1 or 4:1 current balun to go from coax to ladderline..and keep the coax VERY short to minimize losses on it due to high SWR. A choke is for something entirely different.

How about trying to locate the source of the noise? Is it in your house or is it in the neighborhood? It could be something simple like a streetlight buzzing a couple of blocks away. The power company USUALLY pretty good about fixing those kinds of problems. Walk around with a portable AM or shortwave radio and see if you can find the offending pole or whatever. If the noise is in the house, like a dimmer switch, or a tap on lamp, or an appliance, you can fix all that easy enough too.
I'm also wondering about your rigs noise blanker. Most modern radios have pretty darn good NB's. Its not a cure, but it should be reasonably effective, unless the noise is a total monster. In that case, all the more reason to find out where its coming from.

Good Luck K2TL

I am happy with mine. Only thing I can add is that it eats batteries, and my unit does not like to work below 13 Volts. They do sell a tunable bandpass filter for the lower frequencies. I tried a high pass filter - don't bother, it messes up the phase.

A properly designed choke performs the function of a
balun very well - witness the W2DU choke-balun. If
the common-mode currents are choked off in the coax
direction, they must necessarily flow in the ladder-
line direction.

Thanks, Cecil. Guess that's what I'll do. I don't think there is any "graceful" way of going from ladderline to coax.

}}} Sounds like it is actually a UNUN. {{{

I THOUGHT the choke baluns are unbalanced to balanced, and will work OK for the purpose of feeding ladderline. Although they're electrically symmetrical (unbalanced rf goes in one end, and balanced rf comes out the other. Flip 'em around and it's the same, either way).

If they're not, I need to know it so I can go to another kind.

I was half joking. A choke can often function equally well
as a UNUN or a BALUN. A W2DU choke, for instance, doesn't
"know" whether it is in a balanced or unbalanced environment.

>say the difference in noise was profound. He has this loop surrounding his

So, the noise is "profoundly" less (whatever that means), but what
about signals that you want to hear, and how does it perform
transmitting.

You see, a 30dB attenuator would profoundly reduce the noise.... and
the desired receive signals, and the tx signal, but it isn't
necessarily better.

You probably know the answers, you just didn't tell us.

It is often the case that the best antenna for transmission is the one
that makes the most noise where you want to be heard, and the best
antenna for receiving is the one that gives the best S/N ratio (not
necessarily the best S meter deflection) for stations from that place,
and they may not be the same antenna.

Guys, please help me here. You are talking about UNUNs and BALUNs.
A balanced tuner OUTPUT to ladderline is BALANCED TO BALANCED , isn't
it? Why the need for anything, there?

The best part of the (obvious) joke was that it WAS possible as stated, if not probable. That is to say, the physics of the story I saw was indeed correct (assuming he brought up that many tools- which is probably the fatal flaw in the screen play). I think the one I saw had him use an old wooden barrel (easier to break apart upon contact w/ the ground)

_____

Dave,

Here http://www.radio-locator.com/ is a link to a website with calculated coverage areas/contours for US AM broadcast stations. The contours are based on their licensed radiation patterns (directional or not), AND ground conductivities for the geographic regions concerned.

The polar radiation patterns of these stations most probably don't look much like these plots, because of the heavy influence that ground conductivity has on received field strength along the various azimuth bearings.

Even the real coverage contours of AM broadcast stations using omni antennas usually are anything but omni, due to the effects of varying ground conductivities around their various azimuth sectors and ranges.

Have fun.

Roy forgot to mention / stress that a balun is designed for specific impedances. If it is a common 1:1 balun, then it is probably designed for 50 ohms. They are designed for feeding a 1/2 wave dipole or similar antenna, not widely different (from 50) impedances.

Hi Bill, I would go with a wire Log Periodic. There was a series of
articles in Ham Radio Mag. back in the 70's and 80's describing logs
that were made of wire hung from towers. Logs have some gain, and are
frequency independent to an extent. You could construct a Log that
would cover 20-15 meters, and have some (3db?) gain. May 1974 issue of
Ham Radio had such an antenna.
Other options are the various end-fire and broad-side arrays, you
could get more gain, but gain-bandwidth would be limited.
I wish I had your problem:-)

I think from the sound of your description you have one of their
"isolaters" that has a coax socket on both ends.

These things are very neat when used to "choke" currents on the outer
of coax.

>
>Ladderline doesn't adapt well to coax interfaces.

That doesn't sound reliable, the "stick one side of the ladderline in
the center hole" bit, that is. How would you maintain reliable centre
contact. (BTW, you probably already know that 4mm banana plugs fit
into SO-239 neatly.)

What is your problem, is it the "inelegance" of soldering the openwire
ends to the coax plug, or are you concerned about impedance
discontinuity at presumably HF / 6m?

I am sure that you could look around and find adapters, I can think of
a few ways myself, but...

If it is not in the weather, I would just solder the ends of the open
wire to a PL-257 and screw in on. You could sleeve the end going to
the centre conductor to improve its flashover voltage if that is
likely to be an issue. (BTW, taking the earth side wire down inside
the PL259 and bringing it out the braid hole will give you quite a
neat finish.)

Passive rfid transponders can be made with greater range than you have experienced. For instance the Illinois Toll Roads have implemented what they call IPASS. This is a RFID that operates at highway distances and speeds. With IPASS you place the rfid in the center of your car/truck window and when you go through a toll plaza the reader induces an electrical current in the transponder. This current activates the coded transmitter which is read by the plaza receiving equipment. Each and every transponder that passes the reader is interrogated. The induction field is constant and activates the transponder as it is passed.

There is another device called SPEED PASS that is used by Mobile Oil CO. The transponder is contained in a small plastic capsule shaped package. I took one apart and examined the contents. The transponder is contained inside a glass capsule and consists of a small (1/8") diameter coil that is connected to a small pc board with an IC and some other components. The entire thing is about 1/2" long. Range for this device is very short since it is associated with you credit card.

I don't know how big an inductor is needed to provide enough power to transmit over the ranges you are looking at but some simple experimentation should answer this. Basically what the inductor is half of a transformer. The field generator is the other half. The power generated can be used to activate a transistor switch to provide power to the transmitter.

For more information it would be best to do a google search on RFID and see what else is available.

Good luck

Yes, and with a reasonable limit, the SWR on the ladder-line
doesn't matter. IMO, 25:1 is no problem for ladder-line.

Hi Roy,

Your guess is better than mine. I think in order not to bias the results, the solution would have to be that each source is randomly polarized, i.e. the Sun redshifted down into the radio spectrum - coming from every direction. The ring of point sources is an interesting approach. One could use rings at some number of elevation angles, both above and below the plane of the antennas. The greater the elevation angle, the smaller the diameter of the ring such that the radial distance to the antenna is kept constant. But I imgaine you have ideas of your own in this regard.

> it messes up the phase.

If you do want to measure antenna impedance with something like the MFJ and have trouble (as I do) with local broadcasting and other RF, I recommend using a "half wave" filter. This type of filter has reasonable out-of-band attenuation characteristics and doesn't disturb the impedance measurement too much. (Over a limited frequency range it mimics a half wavelength of transmission line.) The impedance disturbance will be the least when the filter is designed to approximately match the measured impedance.

It's simply two cascaded pi sections, with each element having the same value of X. For example, a lowpass looks like this:

```
---.---L---.---L---.---
| | |
C 2C C
| | |
----.-------.-------.---
```

For example, a filter with Z0 = 50 ohms (one which mimics a half wavelength of 50 ohm line) has XL = XC = 50. One designed for 7 MHz would have L = 1.14 uH, C = 455 pF. You can wind the coils on small type 2 or 6 powdered iron cores, and use the closest standard value (e.g., 470 pF) for the capacitors. This filter will cause little impedance disturbance at 7 MHz and, for load impedances near 50 ohms, at lower frequencies also. A highpass looks like this:

```
---.---C---.---C---.---
| | |
L L/2 L
| | |
----.-------.-------.---
```

Again, XL = XC = the filter Z0. Make filters according to your particular measurement needs. You can check the amount of disturbance the filter causes by making a known impedance out of a resistor and capacitor or inductor which is about equal to the measured impedance, and measuring it with and without the filter.

If you can read German, there's a marvelous book describing how to make a wide variety of measurements with an antenna analyzer, with tricks, tips, and details. It's _HF-Messungen mit einem aktiven Stehwellen-Mei¿½gerï¿½t_ by Gerd Janzen, DF6SJ. It's available directly from him at Hochvogelstraï¿½e 29, D-87435 Kempten, Germany.

There must be a host of unstated assumptions behind that statement to make it valid in a limited scenario.

Using TLDETAILS to work up a load of 16+j0 on 100m of Wireman551 ladder-line at 30MHz, the predicted VSWR varies between 25 at the load end and a very modest 6.5 at the generator end, yet the predicted loss is around 6dB. Some might not find that an acceptable loss.

I don't have an accurate number for the entire country, but here in the local area, there is one clear channel station with a single radiator, a half dozen two tower arrays, two 3 tower arrays, five 4 tower arrays that I can recall off the top of my head. If you had asked a dozen years ago, I could have been more accurate. I don't think we have any 5 or 6 radiator arrays here locally, if so, I don't remember them. If my math is correct, that is a 50-50 split, so maybe half have more than 2 towers.

If 100m (325 feet) of ladder-line results in 6dB loss, then a more
realistic 75 feet of ladder-line will result in about 1.4 dB of loss.
That's only 1/4 of an S-unit on the highest frequency HF band and less
on the other bands. That's perfectly acceptable to me and virtually
indistinguishable on an S-meter.

If you have to resort to 325 feet of ladder-line on 30 MHz to try
to prove me wrong, I feel really sorry for you. Why didn't you choose
a million feet to prove me even more wrong? It appears that you are
lurking there in the down under outback just waiting for me to forget
to cross an 'i' or dot a 't'.

Correct, a high SWR is not an issue for ladderline, but the guy was wanting to stick an apparently 50 ohm coax balun right there in between his balanced tuner output and that ladder line. I would think a high SWR, with some TX power, in that device might not do it much good.

My sincere appologies to this thread group. I read that original post twice and still missed that the tuner was unbalanced output. Makes a lot more sense, now.

Close, I make it 2.2dB. (The loss per meter is not a constant figure
in this situation.) Agreed, even that is not a large amount, and
indeed might be quite acceptable in many / most cases.

Cecil, people often employ long runs of open wire feed on HF (ie up to
30MHz), and it just shows that on longer runs, high VSWR can be an
issue for ladder line.

I often hear Rules of Thumb (ROT) like VSWR < 3 is OK for coax and <
25 if fine for open wire, or the converse... but something is lost in
the brief expression of those ROTs, and it seems more and more the
knowledge base of our hobby is the ROTs, rather than the underlying
principles. There is an appeal to the new experts in our hobby to
pickup the ROTs and parrot them... perhaps we need to take the time to
qualify what we say where learners are listening.

Owen,

The problem is that knowing the SWR is not worth much without knowing
the frequency and the spec's of the transmission line.

For example an SWR ratio of 10:1 using a hundred feet of RG-217 on
the 80-meter band is only about 1 dB loss. On 10-meters its a
different story.

I still subscribe to the belief that judging antenna performance based
solely upon SWR is like judging how well a automobile will perform
based solely on what the air pressure is in the tires.

How many hams find a feedline length of 100 Meters acceptable? Lets look at a more realistic length of 100 feet and the loss is less than 2 dB at 30 Mhz. The loss is much less on the lower bands. With all due respect, your example sucks!

BTW, I make your example 2.7dB, not less than 2dB. (Perhaps you labour
under the misaprehension that loss per unit length is a constant in
this situation).

Fred, what you have highlighted is the unstated assumption of some
limit on length. You know enough to choose a length so that the ROT is
true, but does a learner soaking this up know as much?

The REAL problem is that very few people know the SWR on the
transmission line because the SWR meter doesn't measure it.

Aren't you are fooling yourselves?

Reg.

3265. Add WARC Bands - 12M and 17M to Hustler 4-BTV, 5-BTV, or 6-BTV

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-08 04:22:27 UTC
From: Charlie <charlie@play.com>
Message-ID: <11n0a0lhlf0vh02@news.supernews.com>
Source record: 68014
Cross-posted to: rec.radio.amateur.antenna,rec.radio.amateur.dx,rec.radio.amateur.equipment,rec.radio.amateur.misc

Takes about 1 hour assembly time and costs less then $15. Takes legal limit and requires no permanent modifications to original Hustler BTV antennas. SWR on 12M and 17M < 1.2:1 This mod adds a 12M and a 17M vertical radiator on each side of the existing Hustler antenna. Minor retuning of original bands required after 12M and 17M are tuned. It's EASY!

This works a treat and is a great way to get an extra 2 bands from an existing antenna structure.

Unless I missed it, thta quote from the MFJ manual didn't actually say
"The subject is a single-frequency (or even single-band) antenna". For
a multi-frequency/band antenna, isn't ANY feedline ALWAYS going to be
mis-matched on at least SOME of those frequencies/bands?

>>....[snip]....

If those two towers are truly IN LINE with Europe, won't 'most any
antenna you hang BETWEEN them (i.e., from one tower to another, like
a Sterba or several half-squares) radiate 90 degrees AWAY from Europe?

To make an antenna that radiates TOWARD Europe, you could make a "wire
beam" by using a rope or wire strung between the towers as a "boom",
create "elements" by throwing several essentially-half-wavelength-long
inverted-V's ACROSS that "boom" spaced some fraction of a wavelength
apart, use the "element" farthest from Europe as a "reflector", feed
the next one, and use the others as directors. Ergo sum, a humongous
beam "in line" with Europe!

I will have to try your configuration. I did C - L - C/2 - L -C, with
C=1000PF, L=2.2uH. According to SWCad, the gain is flat above 2 MHz, but
there is 120 degrees phase shift at 4 MHz, relative to the phase at 100 MHz.

Michael,
I've had sort of the same experience with a loop antenna. I'd say
it was probably about the same for most everyone.
As far as where to put the balun and how to feed the thing, I
honestly don't think it's going to make much difference. What would be
easiest and 'best' for you? That's how I'd do it...
'Doc

PS - Are loops the 'end-all of antennas? Huh, good question, and the
answer is probably, no. But, I've had good luck with mine...

The problem has symmetry on its side, additional source add to the
dipole in equal measure to the yagi. Adding more power does not
create the missing power already lost.

Source record: 68024

I am a software engineer and I know nothing about hardware
design....

Recently I am asked to collect some information about the components
of
RFID reader that can read ISO-18000-6 (Type A) tag. The tag works in
the UHF
band (860-930 MHz). I have some question but I don't have any friend
that
have RFID experience. I would really appreciate if you could kindly
answer
the questions below.....

1) The operational principle of this kind of tag is "backscatter
coupling". However, I am not sure how the reader distinguish the
forward
signal and the backscattered signal, which of the same frequency. I
read
some information from internet and someone mentioned about the
"directional
coupler". Is directional coupler really used in a typical UHF RFID
reader?
If so, could you kindly recommend a brand and the model number of
directional coupler that can be used in RFID reader?

2) The reader is supposed to be used in a cashier of shop. The range
of
distance of the reader to the tag is about 30cm. Do you have some
typical
power values that the reader need to send and the power of the
backscattered
signal? I need this kind of figure because I was ask to choose the
transceiver IC and I wonder if the power is enough. Do you have any
recommendation of transceiver IC?

3) About the antenna. I found some paper mention about 4 phased
array, which is good for sending RF signal in one direction. Have
anyone used it before? If yes, where can I found it? Any brand name or
model number recommend?

4) Do you have any reference design / paper on the design of RFID
reader?

Thanks in advance.

wrote:

> the solution would have to be that each source is randomly polarized

Hi Jim,

I have worked further with the "random" applications. "Random" is no simple thing as published data has already revealed and my additions, editions, and refinements have not bought much more traction. Putting enough decimal places into the "random" valuations would be mind-numbingly brutal; and as interesting as it would be, it would be a solution in search of a different problem.

If "random" put oil on troubled waters and reduced the 1.4dB discrepancy to say 0.4dB, it says nothing of the original 1dB. And all these machinations to fill the sky with sources so they can look over the reflector of the yagi.... If you pour more water into the bucket, you will eventually fill it, but it won't tell you why the bucket leaks.

However, it is nice to see that the topic still has legs.

The center component should be 2C, or 2000 pF for your experiment, not C/2. The circuit is simply two pi networks in cascade, each having all component reactances equal to the "transmission line" Z0. Each pi section mimics a quarter wave transmission line.

Membership of the Royal Naval Amateur Radio Society (RNARS) is open to all who have an
interest in any facet of amateur radio and who are serving or who have served in the following:

Royal Navy
Royal Marines
Royal Naval Reserve
Royal Marine Reserve
Women's Royal Naval Service
Royal Naval Auxiliary Service
Royal Fleet Auxiliary
Merchant Navy
Sea Cadets Corps
Nautical Training Corps
MOD (Navy)
Commonwealth and Foreign Navies

NON-MEMBERS can purchase RNARS commodities.

Details and membership application form is available online at

first, as a software engineer you need to learn how to use google and other search engines. all the details you are asking about are out there... in excruciating detail in some cases. second, if you are doing software why don't you just go buy the hardware from someone who has already done all the design and testing and just use their system? or get a hardware engineer to do what they do best and figure out what your system requirements need? there are probably dozens of off the shelf rfid manufacturers out there, just pick the range and type of data you need and you should be able to find one that will give you just what you want.

What RF hash level at the used frequency or frequencies can trash the
operational effectiveness of the currently 'of interest' RFID devices
and systems? A watt or two from how many feet away? How many more
watts from how much further away could ruin a perceived 'secure' technology?

Inquiring mind wants to know.

Thanks George,

I am amazed at the number of multi-tower MF antennas in the US. As you say, they are necessary to prevent co-channel interference, day and night, between a large number of broadcasters in the more densely populated regions of your vast country. (Antenna salesmen have had a field day.)

It is also interesting that the whole system is technically regulated by State and/or Central Government. It is not just a free-for-all for newcomers.

I imagine the revenue comes solely from advertisers. Which makes me wonder what percentage of program time is allocated to adverts. Are such matters also regulated? Are any broadcast stations State or City owned?

In this (UK) relatively densely populated country things settled down about 20 years ago. Few MF antennas have more than one tower (or masts as we call them). Although there is much broadcasting at MF for individual cities, most broadcasting takes place at FM VHF where 'capture effects' reduce interference from co-channel transmitters.

It may be of interest that the BBC, still the World's finest broadcasting system, including its overseas services, no longer owns any transmitting stations, Mrs Thatcher quietly sold them off to a private party. Do some Googles for who the eventual owners are?

What matched line loss are you using? The wireman says that line
has about 0.2 dB of matched line loss per 100 ft at 30 MHz. According
to the chart in my ARRL Antenna Book, an SWR of 25:1 at the load
would cause about 1.5 dB loss in 75 feet.

I use a 2Ah NP2-12 with a molex connector double-sided taped to
the underside of the MFJ-259 and charge it with an Astron RS-20M.
The battery is smaller than the MFJ and about 3/4" thick.

I had to increase the 450 ohm tuned section length on my G5RV
to 36 feet to obtain a low 50 ohm SWR (no tuner) on 17m.

EZNEC says the standard G5RV, with 1/2WL of 20m tuned section,
will present an impedance of about 38-j270 to the coax with
a resulting SWR of 40:1. That would be pretty lossy for 75 ft.
of RG8X, maybe even lossy enough to make your IC756 happy. :-)

Following Walt's (W2DU) ideas, I have a 259' horizontal delta (triangle) loop (two trees and a wooden pole) fed at almost middle of one side (convenience, not design) by 450 ohm ladder line. This is soldered directly to a ferrite bead choke balun (ala W2DU) which, via PL-259s and barrel connector, goes to a very short piece of 50 ohm coax (about 6') directly into the house to the unbalanced SO-239 input of my MFJ-941E. Works like a charm on all bands 80-10m, no RF in the room, and good signal reports.

Roy,
I wasn't too clear, but I have 2 T networks back/back. That makes the center cap C/2. I am going to run SWCad on the Pi configuration later, and see what that does.

And Texans are even more so. Ours is the only state whose
flag is allowed to be flown at an equal height with the
US flag. (Some places around here fly the Texas flag an
inch or so higher than that damned Yankee flag. :-) Texas
was the only state having the legal right to seceed from
the USA during the Civil War. The last battle of the Civil
war was fought near Brownsville, TX and the South won.

Reg, I saw a program on "The Discovery Channel:
Ice Age Columbus: Who Were the First Americans?" It
said, based on the latest arrowhead and tool archaeological
evidence, that America was discovered by sea-going ice-age
Europeans 17,000 years before Columbus made his voyage. It
was asserted that some Native Americans still carry the
genetic markers donated by those early Europeans.

$$$ from advertisers ... YEP!

Amount of advertising time is regulated. I can't state with any
authority, but it seems to be 15 to 20 minutes per hour.

Ownership is generally private. International propaganda, err news, may
be indirectly government controlled through a straw man corporation.
Certain public service stations, e.g. WWV, are government 'owned'.

An several additional non sequitor comments. In the USA, although we
claim FREE ENTERPRISE, it is a government influenced economy via
interest rates, international treaties, anti-trust regulations, etc.

Finally, the USA is succumbing to a creeping Socialism. This is contrary
to the words of John F Kennedy: "Ask NOT what your country can do for
you; ask what you can do for your country." Forty-five years after that
statement from President Kennedy a large portion of the population want
the government to do everything for them.

Meanwhile, I measured the impedance of a Drake 100W dummy load with and
without the HPF. All readings without the HPF are within Drake spec.

FREQ NO HPF With HPF

4 Mhz 47j2 33j13
7MHz 47j2 55j3
14MHz 47j1 50j7
28MHz 48j2 47j3
50MHz 49j2 54j11
144MHz 53j11 74j36

Everything was connected with UHF adapters, and no coax was used. Ignore the
VHF readings,. as the filter was not built that carefully. Capacitors are
mica (actual values 1000, 560, 1000), and inductors appear to be 68-2
(2.2uH).

If I get a chance later today, I will rewire it into the Pi configuration
with the same inductors.

Methinks you completely missed Kennedy's meaning. Here's Ayn
Rand's take on that statement: "Ask NOT what your country can
do for you ...", translation: Stop expecting the federal government
to preserve and protect your individual constitutional rights;
"... ask what you can do for your country.", translation: give up
your constitutional rights, including your life, liberty, and
possessions, in order to benefit the welfare state.

Some Texans never wanted to join the United States and it
was a close vote back when Texas was an independent country.
Sam Houston was probably the deciding factor. If Texas had
not joined the US, we probably would still have plenty of $60
a gallon oil. (Inside intel as opposed to Intel Inside(R)):
I once worked for Schlumberger and Texas is definitely NOT
out of oil, i.e. Lots of oil is being held in reserve in
cases of arrested development as it is in Florida,
California, and Alaska.)

And because a current node is guaranteed to occur at least
every 1/2WL, an HF feedline need never be longer than 164
feet, Owen's 100 meter feedline notwithstanding. :-)

It would be silly to expect it to. How much power should you expect to
measure with your instruments positioned in an interference null? This
is the nature of your "leaky bucket".

I am planning how to set up my VHF/UHF station and I need some help.

You can orient a VHF antenna horizontally for CW/SSB work or you could orient that same antenna vertically for local FM use.

What if I am new to VHF/UHF and I want to do both. Could you get a circularly polarized antenna, with both horizontal and vertical elements and use it for both types? I don't want to buy two of the same antenna, only to have one horizontal and one vertical.

What is your advice?

Mount your beam antenna at 45 degrees to the vertical.
You can work both and only lose half an S-unit.

Reg, G4FGQ wrote:
"It is also interesting that the whole system is technically regulated by State and/or Central Government."

In the beginning, there was no regulation. There were only wireless experimenters. Marconi invented the antenna which made the signal go far. Marconi`s antenna may have been seen as an elevated capactor plate. When the transmitter and receiver were each equipped with a plate, you had a coupling capacitor with the earth for a return path. The capacitor carries displacement current while the earth moves electrons.. Then, Marconi discovered the capacitor leads worked well enough without the plates, so plates were omitted.

Marconi was soon using wireless for ship to shore communications. It was essential to safety of life at sea. When the Titanic sank on April 15, 1912, it had a Marconi operator aboard. The world was immediately aware of radio. Inept radio communications during the loss of the Titanic prompted the U.S. Congress to pass the Radio Act of 1912, which expanded on the Wireless Ship Act of 1910 which required all seafaring vessels to maintain 24-hour radio watch and keep contact with nearby ships and coastal radio stations.

All radio communications were in code until Reginald Fessenden invented wireless telephony in 1906. In the early wireless days a lidtener had to understand code to make sense of wireless.

The Radio Act of 1912 assigned three-letter and four-letter codes (call-letters) to radio stations and limited broadcasting to 340 meters. This jammed the signals. From the beginning, the U.S. Federal Government declared sole jurisdiction over radio as the waves don`t stop at state lines and must involve international cooperation. It`s the "Interstate Commerce Regulation Power" of the Federal Government.

In 1920, KDKA in Pittsburgh, a Westinghouse station, transmitted the first commercial radio broadcast.

In 1922, the U.S. Commerce Department allowed powerful stations to use 400 meters, as long as they only broadcast music.

In 1925, A,C. Nielsen began reporting audience shares to advertisers,

In 1925, the first soap opera (The Smith Family) was broadcast.

In 1926, RCA, General Electric, and Westinghouse established The National Broadcasting Company (NBC). NBC operated two networks of stations (Red & Blue).

In 1929, William S. Paley founded The Columbia Broadcasting System (CBS).

In 1931, there were 40,000 U.S. TV sets, including 4,000 in New York City.

In 1933, Edwin Armstrong introduced Frequency Modulation.

The Communications Act of 1934 created the Federal Communicationsd Commission which regulates broadcasting.

In 1936, The British Broadcasting Corporation (BBC) debuted the world`s first television service with three hours of programming a day.

In 1937, Edgar Bergen and Charlie MCCarthy debuted on NBC TV.

We live in interesting times.

Advertising pays for broadcasting in the U.S. except for some public support of non-commercial or almost non-commercial stations.

Program time devoted to advertising on commercial stations was limited by the FCC to just a few minutes per hour before Carter became president. He started the deregulation process which has now run amok. Commercial announcements were the topic of "Saturday Night Live". Satirically, they entertain.

Mrs. Thatcher may have sold the BBC`s distribution facilities, but since BBC has done so well programming, I hope the production facilities are still in the hands of those responsible and that they continue and grow their product.

Who bought the BBC`s transmitters depends on how big the bargains were. If a windfall was readily available, I suspect the Queen, her relatives and allies may have been the buyers. Like Russia, I suppose, except with more care that the buyers seem not to be profiteers.

My daughter lives in London and pays her tax to support the BBC. She now owns a 99-year lease on her flat in Westminster. Only leases are available. The right people are the ownwers and they aren`t selling. Her married name is Edwards too, but her husband is an American. They are both lawyers.

Best regards, Richard harrison, KB5WZI

I am using Wes's characterisation of Wireman 551. Dan's TLDETAILS prog or my online calculator (http://www.vk1od.net/tl/tllce.php) both use (slightly different) models derived from Wes's published measurements.

I don't have the ARRL Antenna Book with me at the moment, but I suspect it is not based on the same Matched Line Loss model, and does not estimate loss from the actual reflection coefficients but from an "average SWR" model which gives an averaged loss per unit length that doesn't take account of the fact that loss is usually highest in the region of current maxima.

My calculator produces a figure of 2.2 dB for your example. I haven't rechecked Dan's this morning, but it is close.

Grab Dan's calculator or mine and try it out. Dan's is really neat and a stand-alone Windows app, my online calc has less graphics, doesn't display (or even calculate SWR), knows about more transmission lines, and only needs a browser to access it. I use them both.

In my 100m of W551 with a 16+j0 load at 30MHz, the loss in one metre of line nearest the load is over 4%, the good news is that since 75% of the transmitter power is already lost, the weighted effect of that 4.3% is nearer 1% of tx output.

If you've cascaded two sections, you have two 1000 pF capacitors in
parallel at the center. That makes a total value of 2000 pF at that point.

That's about what I'd expect. The increasing X with frequency is consistent with a small amount of series stray inductance which is unavoidable in the physical construction. It can be minimized, of course, by careful construction.

A typical homebrew HF filter will begin becoming poor at VHF and above due to series self inductance of the capacitors and shunt self capacitance of the inductors, plus other effects. Component selection and layout can help a lot, but it might be necessary to cascade a VHF/UHF filter with the HF filter if very wideband rejection is necessary. A network analyzer or spectrum analyzer with tracking generator or noise generator are invaluable in solving those problems. Of course, the more stuff you put in the path, the more you're likely to disturb the measurement.

Michael.
Why not try a folded dipole made from 300 ohm TV twin lead? Cut it for the band you are interested in. A tuner or a balun to 52 ohm coax to match your rig will be necessary. I was impressed with the lack of noise pickup from the one I put up a couple of years ago. Cut for 75 meters. My home and antenna are just a hundred feet or so from a power line with 3 sets of high voltage lines and sometimes they are very noisy on a regular dipole, but not the folded dipole.

Paul, KD7HB

I get a lot of noise from my random wire antenna. It transmits very well but is very noisy in receive. My neighbor put up a 280 foot loop antenna which he feeds with ladder line. He feeds the ladder line from a 4 to 1 balun to coax. The coax comes from a tuner. His setup performs very well on all bands down to 75 meters. I went over to his shack last night and listened to his receiver on 75. I was really impressed with the lack of noise. I can safely say the difference in noise was profound. He has this loop surrounding his house at a 30 ft. height. It is arranged in a square.

Has anybody else had this experience with loops? It looks like I have room to put up a triangular loop. Will this work as well?

Can I use the same tuner I have now and just feed a coax into a balun. Or, should I put the balun in the tuner and come straight out with ladder line? There is a lot of room in this tuner. It is an old remote controlled tuner surplused from a ship.

Hi Richard,

Oddly enough, just before a Nanotechnology seminar, I was recently browsing:

"The Radio Amateur's Handbook
A Complete, Authentic and Informative
Work on Wireless Telegraphy and Telephony"

by A. Frederick Collins
Inventor of the Wireless Telephone, 1899

To William Marconi
Inventor of the Wireless Telegraph

"The wireless telephone was invented by the author
of this book at Narberth, Penn., in 1899, and his first
experiments the human voice was transmitted to a
distance of three blocks."

Awarded Gold Medal for same, Alaskan Yukon Pacific Exposition [now the campus of the University of Washington from which I have just returned from minutes ago], 1909.

...

"After Marconi had shown the world how to telegraph without
connecting wires it would seem , on first thought, to be an easy
matter to telephone without wires, but not so, for the electric
spark sets up damped and periodic oscillations and these cannot be
used for transmitting speech. Instead, the oscillations must be
of constant amplitude and continuous. That a direct current arc
light transforms a part of its energy into electric oscillations
was shown by Firth and Rogers, or England, in 1893.

"The author was the first to connect an arc lamp with an
aerial and a ground, and then to use a microphone transmitter
to modulate the sustained oscillations so set up. The receiving
apparatus consisted of a variable contact, known as a pill box
detector, which Sir Oliver Lodge had devised, and to this was

connected an Ericsson telephone receiver, then the most sensitive made. A later improvement for setting up sustained oscillations was the author's rotating oscillation arc."

This volume is available at Project Gutenberg as an e-book. Collins goes on to describe the "boys" who monitored shipping transmissions and often joined in:

"boys began to get great fun out of listening in to what the ship and shore stations were sending and, further, they began to do a little sending on their own account. These youngsters, who caused the professional operators many a pang, were the first wireless amateurs, and among them experts were developed who are the foremost in the practice of the art today."

It should be noted that "hackers" of a decade ago now fill much the same description, and have been similarly elevated.

What the heck is one "metre"? Netscape says that is misspelled and
probably should be corrected to "metro". Why aren't you guys on
the English system?

If the loss in each meter is 4%, wouldn't the loss in 100 meters
be 400%? What am I missing?

3319. Question about free space loss ...

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-08 23:19:09 UTC
From: dougmc@frenzy.com
Message-ID: <Nnacf.82574$GQ.4637@tornado.texas.rr.com>
Source record: 67968

I've got what's probably a pretty basic question about free space loss. I suspect I already know the answer, but I'd like to verify it.

The general formula for free space loss is given as --

36.6 + 20LogD + 20LogF, where D is the distance in miles and F is the frequency in MHz.

Obviously the units don't matter so much -- if you were to change the units, you'd just change the 36.6 value to something else. No problem.

The distance component is obvious -- the power is spreading out.

But what's the frequency component about? Why would increasing the frequency cause less power to be radiated?

My guess is that the frequency factor is _strictly_ something to take into account the effective area/aperature of the receiving antenna, which gets smaller as the frequency increases?

As a more real-world example, if you had a 10 foot diameter satellite dish, aimed directly at a satellite broadcasting (in all directions -- let's assume an isotropic antenna there) 10 watts at 2 GHz, it would receive (ignoring any losses due to the atmosphere) the same power from the satellite if the satellite was broadcasting 10 watts at 200 GHz?

(Our 10 foot dish is most definately not an isotropic antenna.)

As a reference, I'm looking at http://people.deas.harvard.edu/~jones/es151/prop_models/propagation.htm and I'm just verifying my conclusions ...

To use the knowledge I think I've learned to solve the problem I'm trying to figure out, if you've got something that transmits a certain amount of data per second at 50 MHz to a receiver that's 1 mile away, and you wanted to switch to a system that works at 5 GHz but uses the same bandwidth, blindly applying the FSL formula tells you that you'd need 40 dB more power, 10,000 times as much.

(Let's assume that both antennas are both 1/2 wavelength dipoles of the appropriate length for both 50 MHz and 5 GHz -- not isotropic, but relatively close. My frequencies are arbitrary here, chosen just to have a nice ratio of 100.)

But really, since the antenna receives less energy (due to it's smaller size, and it's intercepting less of the signal), the background noise received by it will be similarly reduced (let's also

assume that the background noise intensity is the same at the two frequencies) and so it's just a matter of using a more sensitive receiver, at least until you get to the point where the background noise isn't the limiting factor, and instead the limiting factor is the noise generated by the receiver itself? That assuming all my assumptions are correct (and there's a lot of them, I know) there's little need to increase the transmitted power at all -- just increase the gain in the amplifier in the receiver?

Am I missing something?

The point being what? The observation of the pattern is simply that,
an observation. That a pattern exists is also hardly a revolutionary
concept. That it is the product of many sources does not preclude the
results as physics allows a wave to be viewed as a continuum of
sources along its length.

>
>It would be silly to expect it to. How much power should you expect to
>measure with your instruments positioned in an interference null? This
>is the nature of your "leaky bucket".

When two designs inhabit the same null, as you put it (which is a
mistaken attribution because there are regions with two orders
magnitude less power resolved by the same designs), and one exhibits
more response than the other (regardless of its subsequent
repositioning and that was performed to the degree of 1/80th wave
increments); then it stands to reason one design is inferior to the
other in the capture of a continuum of radiation encompassing them.

This is all displayed in the data offered.

The yagi is that inferior design. This leaky bucket is not fixed by
placing it outside of the "null" (ironically it was very near in a
peak); hence an interference pattern is immaterial to the loss of
power as both designs suffer the same pattern - and equally I might
point out, if other arguments are consistently applied that equal
powers should be exhibited.

Some day the Near East will figure out that USA long term policy is to devoid the Near East of oil. After that, the USA reserves in California, Oklahoma, Florida, and Alaska [Wildlife Refuge] will put the USA in a dominant and controlling position in the world economic situation.

C'mon Cecil, you know it's an exponential decay.

I just started reading this thread. Is the loss in a 'per meter' or 'per wavelength'? In the olden days, we quoted loss as Nepers per wavelength. When did it change to 'percent per meter'?

... or is using a standard horizontal antenna, but happens to be
located in the plane of your antenna. In this situation, he will
"see" only the component of your antenna's radiation pattern - he'll
be in a deep null for any horizontal radiation and may not hear you at
all.

Building an antenna which is omnidirectional, and which also has
substantially equal horizontally- and vertically-polarized signal
components over the full omni donut, is possible (commercial FM
services do it) but seems to be tricky, expensive, and prone to being
narrow-band.

The typical radiation pattern which would ordinarily illuminate an antenna does not have an array of 'holes' in it - symmetrical or otherwise. Further, you can't expect to compare the performance of two different antennas when the field you're exposing them to is malformed and non-uniform. The result would be convoluted (as you have shown).

> This leaky bucket is not fixed by
> placing it outside of the "null" (ironically it was very near in a
> peak);

It is fixed by creating a uniform field. As I said before, integrating the results from a large number of individual point sources (rather than superposing the fields from a large array of point sources) would not produce an interference pattern.

> hence an interference pattern is immaterial to the loss of
> power as both designs suffer the same pattern - and equally I might

This is apparently incorrect, as both antennas should produce the same result.

One wouldn't have to do as much handwaving and fast talking if the field was uniform, Richard.

The maximum HF current point could exist in the first foot of
feedline at the source. Why would the HF losses in the transmission
line at the load ever be greater than at that maximum HF current point?

Hello, I am a newbie in this area of knowledge, I tried to find an answer to my question before posting but I could not. I want to have an extension phone 30 meters in straight line from the base. there are three walls between the desired point and the base. If I take the phone that I have with me (uniden, analog) it works but very poorly. I just need some improvement. I can purchase a 900 mhz dss if this will solve the problem, also, I can conect the antenna from the base to some antenna in the roof (both base and desired point are on the top of a building). Any suggestions?

Well, I would not be raving about his antenna if it also reduced the signals
you want to hear. He gets the same kind of signal reports that I do. We were
both on the same net one night and we were both be received equally at
various spots. Clearly, mine transmits as well as his.
>
> You see, a 30dB attenuator would profoundly reduce the noise.... and

When I listened to our local North Dakota Data Net, I heard all the checkins
like they were much much closer. No Noise! I should have been more specific.
The S?n ratio was profoundly better than my puny random wire. However, I do
not know yet if I am up to putting up 3 or 4 32 foot poles or higher. What a
drag. I will probably do this next spring. It is getting too cold to make
the task a very pleasant one now.

Hi Jim,

Here you are clearly wrong in some presumption. For one, I have done
exactly as you have demanded should be done and you find an error. I
have responded several times to this identical complaint you've
offered, and you have neither offered what that error is, or where I
differ from what you insist in integrating the results. It seems to
me in performing it exactly as you describe it, that I have very
little choice in that matter anyway and barring further elaboration in
how my fulfilling your imperative differs from your imperative, your
point remains rather elusive.

>> hence an interference pattern is immaterial to the loss of

"Should" is the operative word here. "Doesn't" is clearly exhibited.
You don't explain the "Should" and you clearly have issue with the
"Doesn't," but to this point you and others haven't got much to offer.
As I put the challenge to Roy, offer your own model that fulfills the
"Should." Results haven't exactly flown out of that yet, if ever.

>One wouldn't have to do as much handwaving and fast talking if the field
>was uniform, Richard.

A circular uniform field? And one that exists without a pattern of
interference within it? That could only exist at the beginning of
creation reverse filling the void of the cosmos.
THIS is hand waving. ;-)

However, let's just cut to the chase in that you are clearly disturbed
by this "interference pattern" that the tool so clearly reveals. What
about it is so inimical to your expectations? The partitioning of the
problem into multiple sources dates back to Huygens' principle.
Predating EZNEC by 300+ years suggests that the math has more or less

stabilized such that the model confirms it.

Source record: 67830

Yes - the common path loss formula includes the antenna gain.

The gain of an antenna is defined as 4*PI*Ae/lambda^2.

The effective aperture (Ae) of the antenna has units of square meters,
the units of lambda^2 are square meters, so the wavelength dependence
just normalizes area in terms of the wavelength. Otherwise the
definition of antenna gain would change with frequency. That is, a
dipole's gain would double everytime the freuqency was doubled, but
that's not how we define antenna gain. We define the gain of a dipole
to be independent of frequency.

Path loss depends on antenna gain, 1/lambda^2 can be
translated to f^2/c^2, thus the dependency of path loss on f.

Metre: The fundamental base of the metre is the quarter of the
terrestrial meridian, or the distance from the pole to equator, which
has been divided into ten millions of equal parts, one of which is of
the length of the metre.

I think we saw the light before the English, but I think they have a
partial metrication now.

>If the loss in each meter is 4%, wouldn't the loss in 100 meters
>be 400%? What am I missing?

I did not say "the loss in each meter is 4%", I said "the loss in one
metre of line nearest the load is over 4%".

Firstly, percentage losses on cascaded sections are not additive...
you know that. Losses multiply, dB losses add because adding exponents
is multiply the fundamental quantity.

As I have said before, you seem to be under the misconception that the
overall loss (ie Pin/Pout) per unit length of a transmission line
operating with VSWR>1 is constant,

It is not necessarily a constant. It is for a lossless cable, and I
think it probably is for a distortionless cable... but I would have to
check that.

(It is true that the loss per unit length of a transmission line
operating with VSWR=1 is constant.)

We were discussing an example based on Wireman 551 ladder-line. The
dominant factor affecting loss at 30MHz is the series resistance
element. Does it make sense that since in that example, the magnitude
of the current varies by nearly 25:1 along the line, that the I**2*R
loss per unit length along the line is not constant, and will vary by
a factor approaching 625:1?

25% of the power is delivered to the load. There are eleven current
maximum points in 100m on 10m. Does that 11% of the feedline really
contribute 59% of the losses? Does the remaining 89% of the feedline
really only contribute 41% of the losses?

I knocked up a quick graph of the attenuation from point x to the load
for this scenario. (I think / hope it is correct!)

http://www.vk1od.net/lost/W551Example.htm

Is the shape of the curve (the cyclic variation over each electrical
half wave diminishing away from the load, and the general shape of the
curve a surprise? The effects plotted here might not be explained by
the ARRL charts.

When I have written about loss per unit length, I have implied "loss at the rate of y per unit length". If you have tried to apply the 4+% figure to one meter at each maximum, then you are unlikely to get any meaningful results for a number of reasons. See the graph I just posted (our posts crossed in the mail so to speak).

I haven't stated it it the post, but it should be obvious that the rate of attenuation is the slope of the line in the plot referenced in the post.

I don't know what this really means, and how it is relevant to the
discussion that the ROT in question doesn't hold true for longer feed
line lengths.

You have previously dismissed 100m of feed line with the eloquent
"sucks" comment, whatever that means.

What has feeding an antenna at the current node got to do with feed
line length? Is it intended to imply that feed line length or the ROT
are not relevant when you feed the antenna at a current node?

Is it just a trite comment to consume bandwidth?

Sorry, I missed that you had made a T network rather than pi.

In general, a tee network substituted for a pi will have the same characteristics only at one frequency, but will have different transfer and/or impedance characteristics at other frequencies. So the substitution should be done with care if characteristics are important at more than one frequency.

In this case, though, if you make a tee network which has the same "half wave" characteristic as the pi at the design frequency, it'll have identical transfer characteristics (it's got the same filter response) and complementary impedance characteristics. That is, at frequencies where one network has an input impedance greater than 50 ohms, the other will have an impedance that's less, and the phase angles are the negatives of each other. And, luckily, the transformation is simple for this particular special case -- the T network reactances are also all the same and also equal to the Z0 of the "transmission line". So one is just as good as the other.

The HPF equivalent doesn't of course simulate a transmission line, although the impedance transformation though the filter is unity at the design frequency. Otherwise, it works in pretty much an opposite way from the LPF.

I need to correct and clarify a couple of points I made in my earlier posting.

The "half wave" lowpass filter simulates a half wavelength transmission line only at and near the design frequency (where the reactances are all the same). It doesn't do a very good job either above or below that frequency. For a better general simulation of a *short* transmission line, reduce the end pi or T network components to half their values. This model improves -- in theory at least -- as more sections are added. In practice, imperfection in the components limits the quality of the approximation. But I don't think this is of particular interest in making analyzer measurements. The 7 MHz example terminated with 50 ohms will show an input impedance within 2 ohms magnitude and 2 degrees phase of 50 ohms between about 6.2 and 7.4 MHz, so it's good for the entire 40 meter band. But it will disturb measurements on lower bands. You should construct one for each band and, preferably, one for each general impedance level you expect to measure. A single one won't do for multiple bands as I implied.

The HPF equivalent doesn't of course simulate a transmission line, although the impedance transformation though the filter is unity at the design frequency. Otherwise, it works in pretty much an opposite way from the LPF.

I need to correct and clarify a couple of points I made in my earlier posting.

The "half wave" lowpass filter simulates a half wavelength transmission line only at and near the design frequency (where the reactances are all the same). It doesn't do a very good job either above or below that frequency(*). The 7 MHz example terminated with 50 ohms will show an input impedance within 2 ohms magnitude and 2 degrees phase of 50 ohms between about 6.2 and 7.4 MHz, so it's good for the entire 40 meter band. But it will disturb measurements on lower bands. You should construct one for each band and, preferably, one for each general impedance level you expect to measure. A single one won't do for multiple bands as I implied.

(*)For a better general simulation of a *short* transmission line, use a ladder network with all the reactances equal to Z0 except the end components. For the end components, make the series L or shunt C half

the value of the rest. (For example, the LPF I showed would have input and output shunt capacitors with reactance = 100 ohms, and remaining components with reactance = 50 ohms. A five-component tee type network would have input and output series inductors with reactance = 25 ohms, and the remaining components with reactance = 50 ohms.) This model improves -- in theory at least -- as more sections are added, being able to imitate longer and longer lines. In practice, imperfection in the components limits the quality of the approximation. But I don't think this is of particular interest in making analyzer measurements. The model I proposed is better for simulating a half wavelength line while providing filtering.

The graph is unclear. What does it mean that 6% loss occurs at
100 neters? Is that 6% loss per meter at the source? There's 4%
loss at 50 meters. Does that mean the average loss per meter is
4%? Where is the 4% loss in the meter closest to the load plotted?

Feedline length for an average system may be about 75 ft.,
the distance from the antenna to the transceiver. If a
current maximum point occurs at 87 ft., make the feedline
87 ft. long with (usually) no tuner required.

I assume what Fred thinks sucks is your implication that the
average ham feeds his antenna with 100 meters of feedline.
What percentage of hams do you think actually use 100 meters
of transmission line?

Thanks fo sharing. That noise is surely not local: we have powerlines
and industry nearby, LAN in the roofspace, streetlights and so on. I
guess that I'll try a full-wave loop directly laying on the roof,
feedpoint will be low impedance but how low? 5, 1, 0.5 ohms?
Maybe I can transmit to it too if the currents are'nt too high? Is
there an antenna design that has high feedpoint impedance to start
with, so the impedance would be usable when antenna is layd directly to
the roof?

The loss scale is in dB, it is the loss in dB at position x metres
from the load.

If you examine the graph, you will find that the slope of the loss vs
position line is as high as about -22dB/100m at the load, it has a
minimum slope of close to 0dB/100m, and you can see that at large x,
the slope approaches the matched line loss of -1dB/100m.

(You find the -22dB/100m by using a ruler to scale off the slope.
-22dB/100m is -0.22dB/m, or 10**-0.022 which is 0.9506, which
corresponds to a loss of almost 5% in that one metre of line nearest
the load. These aren't mental gymnastics!)

You could calculate an average loss per meter figure, but I don't know
what you could you use it for? The fact that this line is not straight
(as some people seem to assume) means that working with average
numbers is inherently inaccurate.

OK, impedance mismatches not such a big deal. Got it. I am a newbie at this, as I said.

Good article on the sleeve dipoles, thanks for that. Hadn't seen it before.

I think I will just paint the antenna with epoxy or urethane or something to corrosion-proof it. Think a real thin coat of waterproofing will affect the resonant lengths?

Well, I guess you are guessing at what Fred meant. But such a current maximum on the feed point repeats every electrical half wave, and such an approach doesn't preclude using feed lines much longer than 75 feet.

>
>I assume what Fred thinks sucks is your implication that the
>average ham feeds his antenna with 100 meters of feedline.

That is his misinterpretation if that is the case. I did not say an "average ham", but I assert that it is not all that uncommon to have a ham antenna located at 100m or more, and the ROT falls down.

Thing is, about averages, is that the detail you throw away to calculate the average may have been relevant. Further, there is little consolation to the guy who has 10dB worse than average performance because he has used longer feed line under your ROT, to know that a whole lot of guys using shorter feed line are enjoying better than average performance and on average, it all balances out.

It is quite feasible to place an antenna at longer distances if you want, but ladder line should be operated at lower VSWR for acceptable losses, or better feed line used... and the ROT doesn't say that.

It is the unstated length assumption (of apparently 75') of your ROT that makes limits its validity to the people who are most likely to lap it up.

What is an "average ham" now days? Is it one that doesn't have a real interest in the technical side of the hobby, the "I just wanna talk on the radio" set... they like ROTs, gives them something to parrot on air.

3352. Tape Measure Yagi Antenna Questions

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-09 19:49:02 UTC
From: kevin@unseen.org
Message-ID: <1131565742.060922.169080@g14g2000cwa.googlegroups.com>
Source record: 67850

Hi all

I want to build a relatively small & cheap Airband Yagi for receiving only. I have found the Tape Measure Yagi page:

http://home.att.net/~jleggio/projects/rdf/tape_bm.htm

and that seems like a good starting point so have got the bits I need for that (tape measure 25mm width, wooden beam and RG58 Coax).

I have also found this YAGI design page:

http://www.k7mem.150m.com/Electronic_Notebook/antennas/yagi_vhf.html

that looks like it will give me the spacings I need.

However it leaves me with some questions:

What center frequency should i use? Well I guess that depends on the bandwidth of the YAGI I build, and i have no idea about that, is it 1Mhz, 10Mhz is it balanced +10 and -10 or is it +2 and -10, etc. The main frequency I want to receive is 122.7Mhz, airband is 108 to 137 I believe.

I read that for a tape measure yagi I should use an element diameter of roughly half the tape measure width to put into the calculations - is that ok?

The YAGI I am intending on building is about 6 elements, limited really by the practical boom length, however 'officially' this is to small for the calculator above as it is designed for 'long' yagi's - is the calculator above still ok?

The Tape Measure Yagi uses a single straight driven element with a hairpin for matching. The calculator above suggests using a folded dipole with a piece of coax for the matching network. Can I use a single straight tape measure driven element with the calculations from the K7MEM page? If so what do I need to do with the 'hairpin' matching network, how long does the hairpin need to be?

I appreciate there are a few questions here, and that it isn't an exact science, so all comments, suggestions, answers etc welcome.

Thanks
Kev

An SWR meter doesn't measure antenna goodness. The only thing it tells you is how close the antenna's impedance is to 50 ohms, which has nothing to do with the important measures of its performance such as gain and pattern. The best test instrument is a low power transmitter and field strength meter, one at each end of a simulated communication link. For the other end of the link, it would be best to use a setup typical of what you'll actually be using in the field. You'll be able to get some idea of the antenna's effectiveness with over-ground tests, but the ultimate test will be the strength of the signal received over water with the antenna mounted as it will be for the real application. Precise quantitative measurement isn't trivial at all, but qualitative relative measurements are fairly easily made.

You forgot to write - Harumph! ;-)

If you'll read back, you'll find that the descriptions you've provided of your model are far less than effusive and illuminating. No more than a few partial or incomprehensible sentences were provided. We're left to guess most of the details of what you have done. I can only deduce some of it from the results you have provided. I made no criticism of this. You spoke of symmetries and lost power without mention of their nature. So I mentioned their nature. It should have been obvious, but you hadn't even alluded to a possible explanation for this "lost power".

BTW, single sources do not produce interference patterns (unless somehow you're inadvertantly causing diffraction somewhere between the source and the antenna). Each individual source will provide a signal. The amplitude and phase of the signal rendered in the antenna from a single source will depend the position of the source relative to the orientation and construction of the antenna. Summing all the individual signals rendered in the antenna from a multitude of individuals sources does not create an interference pattern in 3 space. It produces a simple magnitude and phase which would hypothetically appear in the antenna if an incoming uniform 'spherical field' existed.

> However, let's just cut to the chase in that you are clearly disturbed
> by this "interference pattern" that the tool so clearly reveals.

I don't find interference to be disturbing. I'm simply pointing out
that we shouldn't expect textbook results from antennas that are
positioned amidst interfering sources. I'm sorry to have perturbed you
with my comments and observations. Any criticisms you may have
precieved should have been taken as purely constructive to the task.
That is my only intent.

Hardly trite, it limits the line length to a maximum of 164 feet.

Hi Jim,

Is that the standard we now measure by? The data is not going to
change and its repetition is not necessary. Do you have something new
to point out?

>You spoke of symmetries and lost power without mention of their nature.

I left speculation to others and you stepped up to the podium.

>So I mentioned their nature. It should have been obvious, but
>you hadn't even alluded to a possible explanation for this "lost power".

Again, this was already offered by me - I may have made a mistake. As
of yet, no one seems interested in pursuing that. Other explanations
would hardly qualify as such, they would be speculations as I've said
and given there is no competing model supporting those speculations -
well, the adage that talk is cheap has had the price slashed by
posting is cheaper.

>BTW, single sources

Demonstrate a single source that offers an inward radiating circular
field. I can anticipate you might be tempted to suggest the
multiplicity of sources accruing from the big bang, but then that
would violate your premise:

>do not produce interference patterns

As I've suggested, all it takes is a positive model supporting a
negation of my results.

>> However, let's just cut to the chase in that you are clearly disturbed
>> by this "interference pattern" that the tool so clearly reveals.
>
>I don't find interference to be disturbing. I'm simply pointing out
>that we shouldn't expect textbook results from antennas that are

Well, then it descends to a population of one disturbed correspondent,
and Roy has yet to resolve his conflict. Your last observation must
emphasize it if we cannot expect a modeler to provide textbook
results.

So, as it stands I see that no one has a competing model and the data remains an enigma to most.

Aha, I see that noted at the bottom now that I scroll down.
It didn't make sense to me if the loss scale was in percent.
So what do I get if I integrate the area under the curve?

Incidentally, I was engaging in fuzzy republican thinking when
I came up with eleven current maximum points in 100 meters of
feedline. Of course, there are twice that, i.e. 22 current maximum
points which can be counted on your graph.

> You could calculate an average loss per meter figure, but I don't know
> what you could you use it for? The fact that this line is not straight
> (as some people seem to assume) means that working with average
> numbers is inherently inaccurate.

Owen, most hams are not rocket scientists like you :-) Quite
often, a rule-of-thumb average beats total ignorance. All
measurements contain errors and are inherently inaccurate.
Some of us live with that reality. Some of us rant and rave
about it. Next time you are on your motorcycle, note that
your speedometer is "inherently inaccurate" as is your gas
gauge as are your reflexes. If you are not inherently inaccurate
throwing darts in the local pub, you are a very unusual homo sapien.

I, for one, am satisfied with average losses, presumably averaged
over one half wavelength. The way I came up with that 25:1 limit
on my open-wire SWR is that 600/25 equals 24 ohms and that is an
acceptable impedance to my IC-256PRO's autotuner. Noting that the
losses in 100 ft. of open-wire line running at an SWR of 25:1 are
acceptable was an afterthought.

Nope, not a guess. Fred and I are on the same wavelength. :-)
We use the same "notuner" method for resonating our antenna
systems.

> That is his misinterpretation if that is the case. I did not say an
> "average ham", but I assert that it is not all that uncommon to have a
> ham antenna located at 100m or more, and the ROT falls down.

But it is indeed extremely uncommon for an *American* amateur
radio operator to have a feedline that is 100m long. I personally
know of only a handfull of cases in my 55 years of hamming and
most of those involved getting vhf/uhf antennas to the top of a hill.

> Thing is, about averages, is that the detail you throw away to
> calculate the average may have been relevant.

It may be relevant to a "rocket scientist", such as yourself, and
completely irrelevant and indeed beyond the understanding of the
average ham who must necessarily rely upon rules of thumb.

> It is quite feasible to place an antenna at longer distances if you
> want, ...

~99.99% of hams don't want to. Why make things more difficult?

> It is the unstated length assumption (of apparently 75') of your ROT
> that makes limits its validity to the people who are most likely to
> lap it up.

Sorry to disagree, the great majority of "people who are most likely
to lap it up" are people with 60-100 foot feedlines. Most assertions
on this newsgroup are in the context of the average ham.

Owen, it's obvious that you deliberately picked 100 meters to try to
prove a point that you couldn't make otherwise. You chose an inferior
ladder-line that I wouldn't even allow on my property. Your attempts to
save face by dragging the discussion down some primrose path involving
minute details is interesting but not interesting enough to follow
you down said path.

I chose 100m as a round number that is practical and long enough to demonstrate that at very high VSWR, the approximations that might hold for shorter lengths and lower VSWR are no longer valid. Open wire feeders well in excess of 100m are practical, but ladder line with very high VSWR isn't.

(On the other hand, your 75' "standard" is about enough to reach the feed point of a medium height antenna directly above the shack, and might be argued as a minimum practical length for a good antenna.)

The ladder line I chose was one of the four that have reasonably good characterisation (by N7WS) and it wouldn't matter much which of the four you chose, they are fairly similar... I chose the first one on the list. (The last one on the list, 554 with 25:1 load SWR give 5.6dB against 6dB or 551... I wont bother checking the others.) No, I did not deliberately choose an inferior ladder line.

I appreciate all the comments very much. A folded dipole would be easier for me. I will discuss this with my neighbor W0BBN. He has been using a loop for 20 years. It sounds like it is hard to go wrong if you are willing to put out the work for a loop antenna. I have been away from low band work since I started college. That has been very very long ago. I had never hear of a loop antenna back in the 50s. There was no internet and other hams were few and far between where I lived in the country.

>calculator above still ok?
>
No. The first 6 elements of the DL6WU yagis on that page are
specifically optimized to be the start of a much longer yagi. On their
own, they would not make a good 6-element yagi.

If all you want are 6 elements, look for a 6-element design. There is a
good example at:
http://www.ifwtech.co.uk/g3sek/diy-yagi/dubus/bvo6.htm

Also try searching www.cebik.com for "owa" (Optimized Wideband Array).

You are unlikely to find a design for the particular frequency you want
to use. Modifying designs to a different frequency requires is basically
about building an exact scale model, with all its dimensions scaled to a
different wavelength... but I do mean *all* dimensions. This often isn't
mechanically practical, and if you change a key feature like the element
diameter, the diameter of a metal boom and/or the element mounting
method, then all the element lengths will need to change as well.
There's a program to help you do this on my 'VHF/UHF Long Yagi Workshop'
page:
http://www.ifwtech.co.uk/g3sek/diy-yagi/index.htm

Yagi performance falls off quite rapidly above the design frequency, so
if you want to cover the whole band, you should design it for a
frequency towards the high end.

From that same page, you'll also find some practical construction tips
(although I'm not personally familiar with the tape measure
construction).

[...]
>
>I appreciate there are a few questions here, and that it isn't an exact
>science, so all comments, suggestions, answers etc welcome.

Yagi design is quite an exact science. The art *building* yagis is to
let the science work :-)

hi

I noticed the below lately and wonder, being new at this ... how one would measure it?

is their a step by step guide or just a specific instrument(s) you need

I'd love to learn and try it, but didn't see any posted ''instructions''...
any help appreciated

m

partially cut from the arrl's email
"Returning to the airwaves November 17 at 0245 UTC (Wednesday, November 16 in US time zones), the 2005 ARRL Frequency Measuring Test (FMT) once again will call on participants to measure the frequency of an audio tone modulating the carrier.

''Measuring the tone frequency, as opposed to that of the carrier, reinforces the understanding of the relationship between carrier frequency and the actual components of a transmitted signal,'' Engineer and ARRL Contributing Editor Ward Silver, N0AX, says in ''Tune In the 2005 Frequency Measuring Test,'' in November QST (p 54),...www.arrl.org/w1aw/fmt/2005/05fmtsilver.pdf. ''With the carrier largely suppressed for SSB signals, only the sideband components remain. A single modulating tone results in a single transmitted component.'' But, Silver notes, the frequency of the absent carrier is what the operator sees on the radio's display.

The FMT signals will emanate from Maxim Memorial Station W1AW this year on 160, 80 and 40 meters. The 20-meter transmission has been dropped for 2005 because of the generally poor conditions during evening hours on that band. The frequencies will be 1855, 3990 and 7290 kHz, and all transmissions will be on lower sideband (LSB). The FMT will replace the W1AW phone bulletin normally transmitted at 0245 UTC on November 17 (November 16 in US time zones).

Participants may utilize either direct or indirect techniques to determine the tone frequency. ''Direct measurements assume a carrier frequency and measure the audio tone frequency directly,'' Silver explains. ''Indirect measurements obtain the transmitted frequency of the tone component at RF, then compute the difference between the published carrier frequency and measured frequency.''

Silver advises that since the W1AW exciters are independent units and not fed with a single local oscillator, participants can expect

the measured tone frequency to differ slightly on each band.

The test itself will consist of three 60-second tone transmissions on each band, followed by a station identification. The whole test will run for about 15 minutes and will end with a station ID.

Submitted reports should include the time of reception and the tone frequency. Those using an indirect measurement method should show how they calculated the tone frequency. Participants also should include name, call sign and location in their reports, and they may submit separate reports for each band. A Certificate of Participation is available to all entrants.

hi kevin,

Since you're interested in a 2 element yagi for reception only,
how about a Moxon antenna ?

You can use aluminum rod and pvc, takes up less space
then the Yagi but almost same performance.
Or try it with the tape measure for elements.
Direct fed with 50 ohm coax.

http://www.cebik.com/moxon/moxbld.html

Here is a calculator to help build a Moxon for a given frequency.

http://www.cebik.com/moxon/moxpage.html

Good luck!

jimbo

Hi Myles,

You don't see instructions because you are supposed to work this out
for yourself and then report both your results and HOW YOU DID IT.

It should be a slam dunk with a PC sound card being run under an FFT.
However, the skill part is tuning the sideband (and then it remains
only the skill of reading the frequency setting of your rig - any
error is probably going to be there).

Richard Clark, KB7QHC wrote:
"---by A. Frederick Collins inventor of the Wireless Telephone, 1899."

Collins apparently connected an arc lamp to an arial and ground, using a microphone transmitter to modulate the oscillations it set up. I suppose a carbon button in series with the d-c to the arc would do that.

Success has many authors. The airplane had many builders around this productive era, but it is the Wright brothers that are credited with the first practical success.

Fessenden was a Canadian who happened to be Chief Engineer of the Radio Corporation of America, successor to the American Marconi Company. Fessenden holds more patents than aqnyone except Thomas Edison, who once employed Fessenden. Fessenden`s modulation method was control of the excitation of an r-f alternator by a magnetic amplifier which he modulated with audio, speech, music or whatever, even dots and dashes. Modulation of high r-f powers was commonplace. Hundreds of kilowatts were produced and modulated by the Fessenden method. A relic of the era in Sweeden is still revived annually for demonstration, I believe.

Best regards, Richard Harrison, KB5WZI

As opposed to the standard full height backyard antenna with 100 meter
feedline which would then be something more like this:

http://www.kkn.net/gallery/hcjb/hc15

Years ago, I was faculty advisor of a thesis containing a viable technique
for measuring the carrier of a SSB signal modulated by a human voice when
the carrier was nulled. The student's name, as well as I can remember, was
Day and his first name was something like Louis.

Should be a link to it somewhere.

The scheme took advantage of the nature of the human voice. It required one
to have the means to inject a carrier (which was measured by conventional
means) and to look at the recovered audio on a scope.

The old FMT had one measure CW signals. They were great fun.

This looks like a guessing game / lottery to some extent, since no information is given on the stability of either the virtual carrier or the modulating tone (yet you are advised they both may vary) and the time of measurement (an instant?) is part of the submitted data.

The winner using a sound scientific approach to measurement may require luck to be not beaten by a less accurate, but closer answer at some moment.

Source record: 67778

An outside loop works very well for nulling the noise and still
allowing you to hear the weak stations.
In most if not all of the ARRL Antenna Books, there is a chapter on
a 160 meter receiving loop, you can just scale this back for 80m.
I dont have the book here now, I think the lenght was something like
25' or so for 160m.
It is made out of a 75 ohm piece of coax that goes around once,
connected to a air variable cap. The braid of the coax is cut at a
certain point in the loop.
Its not that big at all even on 160m and can be put up on a pole and
turned by hand or even by a small TV type rotor.
On 160m with terrible local power line noise I was able to hear many
stations including DX stations on the loop that I could never hear on
my Inverted L transmitting antenna on 160m.

Hi Mac,

Well, I remembered one link with Colorado in it:
http://skyraider.org/skyassn/gbookf250.html
which contains an entry (looks like a guest-book thing):
Name: Lucius Day
Website:
Referred by: Just Surfed On In
From: Denver Colo area
Time: 1999-01-14 07:51:23
Comments: Flew "Robinson" EA-1F's (VAW-13) Cubi, Kittyhawk,
Ranger, Saigon

These last comments make it appear this Lucius (of Colorado) was a
Navy pilot during the Vietnam era. loubd@day is the associated email
but the address is hardly complete and appears to be one of those
quick, dismissive entries to satisfy a login request.

3386. Re: Tape Measure Yagi Antenna Questions

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-11 14:28:46 UTC
From: kevin@unseen.org
Message-ID: <1131719326.938268.317050@g43g2000cwa.googlegroups.com>
Source record: 67782

Hi Guys

I have to admit I am struggling a bit here. I looked at the scaling option, but the program you pointed to didn't seem to cover all the variables required to be scaled.

So, rather than admitting defeat I tried to build a 6 element using the dimensions from the k7mem link above using tape measure for the elements and a wooden boom. However I didn't know what to do for the driven element, both in terms of width (how big a gap in the middle and how does this alter the overall width of the element) and matching network. Currently I have about a 1 inch air gap, which makes the total width about 1" wider but the width of metal is the same (I don't know which is relevant?). Currently I have no matching network of any kind, just connected straight to the coax.

This doesn't work, it is probably worse than a rubber duck! So, I'm after some help please, what should I do for driven element width and matching, and what should I do about element widths and spacings (I can redo them if I need to)?

Thanks in advance.
Cheers
Kev

3387. Am reception

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-11 14:35:15 UTC
From: Jeff Dieterle <jdieter@nospam.carlnet.org>
Message-ID: <11n9b1ak6fquaaa@corp.supernews.com>
Source record: 67783

Pardon me if this is the wrong group to find some answers. I'm using a GE Superadio III and would like to receive 2 frequencies. AM670 from Chicago and AM1070 from Indianapolis predominantly night time listening. I work inside a factory and can't receive either of these unless I get near an outside window or go outside.

I'm considering buying a tuned loop for these 2 frequencies from http://www.amradioantennas.com/. He's quoted me a price of 85 us$ including shipping and insurance. Does anyone have experience with this type of tuned loop antennae. I've ran RGU-6 coax from my office to the factory roof, (appx.75ft) as I doubt if the loop would pull these in from inside my office which is inside the factory.

Is there a less expensive alternative than the loop since I have coax installed ?

Thanks
Jeff

Jeff,
I think the first thing I'd try would be to just add a length of
wire to the end of the cable on the roof. If It does any good, add a
longer length of wire and see what happens. Is it a 'cure-all'? Nope,
but certainly easier/cheaper/faster than getting a loop antenna...
'Doc

Just tie an external wire to the coax center
conductor and try it - may not work but it
doesn't cost much to try.

I have a similar loop from C.Crane company. It works well. But these
loops need to be in close proximity to the radio's built-in antenna.
Simply putting the loop up on the roof at the end of the coax won't do
any good. Using the loop indoors, inside the factory, would be a crap
shoot... don't think it would be worth the $85. I'd look at some sort
of outdoor antenna, as others have suggested.

Hi Jeff

The 75 feet of coax between the outside antenna and the radio will also be
a capacitor shunting the signal to ground across the front end of the
receiver. That can be a serious loss of signal at AM frequencies.
An amplifier on the roof is one solution.

It is fairly easy to build a loop so that concept can be evaluated prior
to spending the $85. You are aware that the tuned loop on the roof will
require the antenna to be adjusted for each of the two frequencies you want.
Is that practical for your application?

Jerry

Did you connect the coax to anything at all, or is it just coax
going outside to the roof,
Connecting it to the metal gutters or something like that might really
help the reception.
If there are no metal gutters or anything like that, connect a long
piece of wire to the center conductor of the coax and lay it out on the
roof.

You might also try just taking a piece of wire and connecting it to
the back of the GE SRIII, connect it to the AM screw terminal on the
back of the radio and take that wire over to the window and see if that
works, or you can continue that wire all the way from the back of the
radio all the way out to the roof.

I also remember something like winding wire around something like a
Quaker oatmeal container, contecting both ends of this wire to a small
air variable cap and just placing this antenna right behind the GE SR,
near its internal antenna. You can then tune the cap for peak reception
and then turn it and the radio to get the stations you want, this coil
of wire enhances the internal antenna of the GE SR.

I dont have the article but Mr Cebik has written about it and how it
works. www.cebik.com/edz/edzfeed.html

I built a version for 6m and it's very good for simple wire and it
also resonates as a dipole at 17m.

Hi Dave,

I have the CommQuart issue that has Rick's article. However, it's the Fall issue, not the summer. I'm in the process of scanning it for you. Give me a few minutes. Is the mail address shown above the correct one for email?

Hi, Walt! I just received the article I was thinking of (pages 104
and 106 of the Summer '97 Communications Quarterly) from another ham.

If that's the same article you have, then no need to send it. If
there's another version in the Fall '97 issue which is different, then
I'd love to have it as well.

The EDZ described in the Summer issue is an interesting one. It's a
lot lighter in weight than the only other 2-meter EDZ plans I've seen
(the latter being a copper-pipe variety with a different matching
and balun arrangement).

Both look like useful designs, although since they're long and require
side-mounting from a mast or tower they're probably less convenient
for home use than ground-plane or J-pole antennas.

Yes, my email address is correct.

It sounds similar to a recent article. I see that in the July/August QEX there was an article called "A Blind Automatic Frequency Control Algorithm for Single Sideband" by Geissinger. I can't find that issue, so don't know it used Mr. Day's technique or not.

I have used elevated 4-square vertical arrays and elevated verticals for years on 40 and 80 meters. Performance seems just fine on them. However one very serious issue remains, as far as my experience is concerned, for using them. You, MUST provide some decent lighting protection for them as to how to avoid the step voltage that appears on the whole system because of the elevated radial and feed point positions above ground during strikes and even nearby hits. Even a ten foot height above ground for a 40 meter vertical, with four tuned elevated radials at that height, is a huge voltage point up from true ground, considering the large RF currents in the strike. If your feed line is in any position to be involved in that elevated voltage position and can carry part of the strike dissapation back into your shack or home, you can really get hurt.

I found out a long time ago, that the best way to protect my equipment with elevated HF verticals is to carry the entire feed system back to ground level where I can incorporate Polyphaser or other gas tube protection at that same ground level I'm using to sink the strike at the arrays. Then I bring the feed line back to the physical structure at GROUND level with appropriate protection at the structure site entrance, sinked to ground as well there.

Since incorporating that technique, for many years now, and I take an average of a direct hit on my 80 meter array at least once every year or so, I never have lost anything on the HF station, even though it is on line 24X7 all the time, and some parts of it are remote operatable as well. With complete pig iron equipped industrial rack computer systems and so on, even they have survived completely for years now that way too. But not switching power supply stuff, as I've found out sadly.

I take more damage, whatever, from direct hits on the neighboring power lines that sink back to my facility good ground systems, at this point. The worst damage for years is oddly on the phone system lines. Even with protection at

the entrance point, there is still enough inductace ramp-up on these low level circuits, that I'll see blown fuses in the phone line protectors from time to time, and rarely, even yet, modem failures, even with that done!

Again, my best advice if you want to go your way with the big elevated vertical, is to carefully consider how to mitigate the strike effects for not only your ham gear, but the rest of the dwelling as well. Remember, even ten or twenty feet is a real length for getting surge voltage, when true ground is underneath it. And where things are connected at a junction point which can carry part of the surge current off on a 'parallel' path to a different ground sink point you might not have considered.

The loop is a DC short and is very quiet. You can also feed it with a quarter wave section of 75 ohm coax using (quarter wave length x Velocity of coax) as the length of the matching section.

Good luck,

Michael, a horizontal full-wave loop is actually quite a good choice for LOCAL networking on 75m. The feedpoint impedance will depend somewhat on the distance above ground and on the quality of the ground but should range between about 200 ohms down to as low as about 50 (or even lower if your ground is good). The shape of the loop is not all that important and, if it's symmetric, the feedpoint can be anywhere. The ideal height would be about 65 feet, but lower will still work well.

The radiation characteristic of an antenna like this is horizontal polarization but with the main lobe directly skyward (which is actually a good thing on 75m for LOCAL work). It does this, of course, at the expense of radiation at low angles, so it is not a useful DX antenna (though it may outperform a dipole at the same height). Being a loop, it is also somewhat immune to near-field electrostatic interference such as from nearby power lines (which may account for the lower noise pickup).

Check this page:
http://www.qsl.net/df3lp/projects/vertical/index.html

"Do not mount groundplane antennas at heights between 0.25 and 1.25 wavelength. At those levels above ground most of the energy will be radiated at angles of 27° to 45° into the ionosphere. This phenomenon seems to be independent to the number of radials or other counterpoises. Further simulations indicates that this is true for all other variants of vertical antenna systems too. "

As I explained one night (on 75m from Halifax) to G5RV, his antenna is
essentially a dipole of non-resonant length with a mismatched feedline that
is used as a tuning section. My preferred method of using antennas of that
nature is to put a 300ohm line on the feedpoint and simply tune it in the
shack with a good, balanced tuner. The antenna will then perform well on
any frequency the tuner can match.

I've been seeing pictures of these weird antennas for years. Near as I can tell from the picture, it's essentially a heavily-loaded very short dipole with two large capacity hats at the ends. But it's impossible to tell from the pictures what the exact configuration is. Can anyone tell me exactly what's happening? Is the mast part of the radiating system? The feedline? The literature (including the manuals) sort of implies that it is.

Also, from the pictures, I get the impression that the standard mast-mount configuration is mostly vertically polarized. This would certainly account for reports I have read that the antenna is a bit of a dud at short range on 80m.

If someone has a computer model for it for MMHAMSOFT's modeller, that would be GREAT!

The reason I'm asking is that I'm in the process of trying to design something really low profile for a second floor apartment balcony for 75 and 80m.

Message-ID: <78ydnb1E5L2fxOveRVn-gg@comcast.com>
Source record: 67805

I have a Alpha Delta DX-A 40 80 and 160 antenna, feed point
is up 35 ft. I an comparing it to a W9INN 40 80 160 and it's only up
28ft.

My question is when running a ballun as the W9INN antenna does.
Can it be hung right to the tower leg or should it be on a stand off.
To keep it away from the tower legs buy 3 ft.

The Alpha Delta DX-A wants to be hooked right to the tower leg.

There seems to be no difference between the both antennas
with the exception the W9INN antenna is set more to the middle of the
phone band for 40 80 and 160 were the Delta A is not .

TNX for any input.

Steve

Is it better than just feeding it with about 15 inches of ladder-line?

Better? Dunno - maybe so, maybe no.

The K1BQT design creates an EDZ using a pair of 38"-or-so rods or
whips, and two just-under-10" lengths of RG-58 solid-core coax
(conductor and braid shorted at the outer end, braid left open at the
center where the antenna connects to the feedline). The lengths of
RG-58 act as inductive stubs, cancelling out the capacitive reactance
of the radiators; the lengths of the rods/whips are adjusted to yield
a 50-ohm-per-side resistive impedancea at the feedpoint. The
resulting 100-ohm impedance is matched to the feedline by a 3/4-
wavelength piece of RG-59 75-ohm coax which is coiled around the
center support... it serves both as an impedance transformer and a
choke balun.

If I were going to feed a 5/4 with ladder line, for tower
side-mounting, I suppose I'd probably put the ladder line inside the
PVC support arm, and then connect it to some 50-ohm coax which was
wound around the outside of the arm to create a choke balun.

Cebik's stuff is probably for HF. EZNEC sez an 8 foot long, one
inch diameter dipole at 36 ft. height has a feedpoint impedance
of 86-j91 on 146 MHz. Heck, that's already better than some rubber
duckies. All it takes to resonate that impedance to a 50 ohm SWR
of about 1.6:1 is about 2.5 inches of 450 ohm ladder-line in
series. What could possibly be simpler than that?

Steve -

When I used a push up tower for my inverted V ... I used a stand-off similar to the IIX SO-1 standoff bracket -- to get the antenna away from the push up pole and another tower.

IIX Equipment has pre-made assemblies that will work with most towers.

Yes, more effective than the Isotron but disappointing, nevertheless
(been there done that). A balcony-mounted mobile screwdriver is still
pretty far down from a properly designed small loop on 75m. However,
a vertical longer than a mobile screwdriver would be something worth
considering. I think HighSierra has one of those.

With EDZ or it's evil twin in the other plane the 5/8 wave the
electrical length affects feed point R while the X is fairly large.
So you use some form of matching magic to transform that
unrulely X to R and thereby a match to a 50 ohm source and line.

If you looked at the Cebik article you will see how and why
plus it's result at 2m. I scaled his work for 6m and it worked
to the the decimal point.

1/2" Superflex (FS4J-50B) is pretty low loss at 900 MHz, but it ain't exactly supple. How long is the coax run? RG-142 might be OK for semi-short runs and is fairly flexible (about the same size as RG-58)...

Actually, I *am* thinking outbacker or MFJ. The balcony is large and
aluminum-railed, which should actually form a decent counterpoise if it
doesn't blast my sat. TV and 2m stuff all to heck.

I just wondered what the theory is with the isotron. If it's actually
exciting its mast (as some antennas do), then maybe I could use a similar
technique to excite the balcony rail itself.

A loop is not out of the question either, but to be at all efficient, it
would have to be made of 1" or even 2" copper pipe.

Or if the system can play at 75 ohms, satellite TV grade RG6 is pretty fair
and cheap to buy.

Unless you go for exotica thin low loss coax at 900mhz is a
contradiction in terms.

RG58 at 900mhz is a dummy load after about 15ft. (20db/100ft)
Belden 9914 is around 8db/100ft (.400inch size)

RG8X is a low loss .242" cable thats only 12db/100 at 900mhz
so if you use that and stay under 20ft the loss should be be under
3db still lossy but manageable. Generally if you want low loss cable
at 900mhz you are talking about fat or very expensive cables.

Sound like your discribing my station setup. I also use a Delta loop in the shape of a diamond with the highest point at approximately 70 feet and the lowest opposite corner is about 40 feet, both above ground. Now it gets interesting as this set up is likely about 5 feet lower than the closest neighbouring amateur's basement floor is and I still out perform his inverted V. But the my loop is a full wave on 80 meters and I have a rather uneak piece of property. My soil is very good conductively and my ground happens to be a creek bed with a 8 inch water pipe submerged in the creek which runs all year round with about a foot of water over the pipe.
Also when I was looking for property I drove my van in to the property as far as I could and call CQ on my mobile hf. Made a contact in Glasglow, Moscow and Japan. I bought the property that afternoon. And I haven't stopped enjoying the bands even when we are at the low side of a cycle. I've also played with a number of antennas and always came back to the delta loop or a four square. I'm planning on putting up a full wave delta loop for 160 meters this spring. My present loop is hooted up to a homebrew 4:1 balun with 300 ohm foam then a 10 foot piece of 9913 coax to a At-180 Icom tuner to a IC-706MKIIG. On a bad night I can make contacts about the Mississippe to Hawai, on a good night Europe and the Globe. If you have the room they are one of the best antennas for the money invested. But you still have to have a good location and a good ground, if your missing either there isn't an antenna in the world that will help you. By the way I'm 147 feet above sea level and my closest neighbouring amateur is 177 feet and his antenna is 30 feet above that, but I still out preform him hands down on any and all bands.

Anyway this is what it's all about, haveing fun and making new friends.

LMR195 uses the same connectors as RG58, and has about 11dB loss /
100' at 900 MHz. You should find it stocked in the WLAN outlets, with
or without connectors.

Another thought is to salvage some foil/foam RG58 style cable from a
car mobile phone antenna.

The INN is a lot easer to tune for band. But for signal reports
they both seem the same. I had a friend follow me around to all bands
to compare and they both seemed the same.

My question was about the feed point. Should it be on a stand off
on the tower to get the balun away from the tower ?

Steve

If you listen around the bands you hear talk about the INN wire
antenna. You can't get them anymore because the guy passed away.

Hey Charlie,
I have a few of them. One in my truck has about 200,000 miles on it,
from a few Ford Explorers...
It seems to tune well. My antenas are typically bug catchers but also
have one in my Chrysler LXI minivan. A great little tuner. I would
also look at the MFJ, but I have not personally seen or tried it.

I've been looking for an EZNEC model of the Isotron for the past 6 months, Dave. I haven't found anybody who has modeled one. I understand the Isotron is "lossy" and "nothing but radiating feedline" but it would still be interesting to see it on a grid or check the numbers in NEC. And - just like every antenna, you'll find people who use these things and love them, proving that "the best antenna is one that works for you". I've got to agree with what others are telling you. A small loop is the best performing antenna I've been able to find for my very challenging antenna environment. Other than the small bandwidth, I know it's working better than any inverted-vee or shortened dipole I've ever been able to get up amid the power lines and CATV cables here.

Good luck.

"The Guy" (W9INN) was William E. "Bill" Fanckboner, W9INN, of Mt Prospect,
Illinois, about 10 miles north of my QTH.

Bill was the sole proprietor of W9INN Antennas and died July 30, 2004. He was 80.
His daughter, Robin Randall, shortly after this death decided that the W9INN Antenna business would die with him. "Dad did all of the work by himself, so it is effectively out of business, he was the business." "He was working full time until a week prior to his death".
Refunds were mailed to those amateurs with existing orders.

A long-time ARRL member and supporter, Fanckboner turned his talents for radio and electronics into W9INN Antennas some three decades ago after working for Motorola, and he was a regular QST advertiser.
Fanckboner designed and hand-built custom antennas, including the MPD-5C-78, MPD-2 and MDX-8C "hideaway" dipoles, and, his daughter says, Fanckboner enjoyed a reputation within the amateur community for skilled workmanship and a friendly, helpful manner. A memorial service was held August 9, 2004. The family invites interested customers that memorial donations may be sent to the American Cancer Society in his name.

Hi Jim

I wonder why you would not use the RG-6 as suggested by Dave Oldridge.
Even Home Depot has the cable and the BNCs for it.
RG-6 is good transmission line at 900 MHz.

I submit that nothing in the system from the antenna all the way to the
receiver will be 50 ohms, no matter what transmission line you choose.

Jerry

LMR-1700 looks pretty good on the loss charts. It's about
$10 per foot, 1.67 inch diameter - not sure about the BNC
connector :-)

Is the balun mounted in an aluminum enclosure? If so, it's probably OK
to fasten it to the tower assuming the tower is not RF 'hot'.

It's a W2AU Balun that came with the antenna. I took a pulley and attached
it to the tower and then
took a line and attached it to the Balun so i could raze and lower it for
adjustments.

So the Balun is about a foot away from the tower.

It seems to tune ok all readings are below 2.1 on center freq on phone bands
on 40 80 160.

Just wonder if it's hearting the transmitting.

Thanks for the input..

I suggest you look at a BNC cable assembly available From AAA RF Products of San Clemente, CA The AAA1003-180 Cable Assembly uses RG213/U cable with BNC male connectors, lenght is 15 feet and loss at 900 MHz would be about 1.6 dB. Cost about $30. See www.aaarfproducts.com for email & phone #

If you need a nice low-loss coax for 900 MHz, there's not much better
than a 1" outside diameter cable with a 0.3" diameter inner conductor.
Or something like that.

If you cannot find such a line then the best thing to do is re-design
the whole system such that you don't need it.

I actually have a fairly good ground--a balcony rail that forms an
aluminum grid about 40 feet in length and 3 feet in height. That's bound
to have a decent capacative coupling to real ground inside the building,
even if the rails are bolted into wood.

I can't speak to the AT-1000, but I have an AT-100 and I LOVE it! It simply remembers any frequency I "visit" and when I return to that band/frequency, it is there, and I mean right NOW! I am not a fan of "tuners", however due to the civilian and military frequencies I am authorized, I simply couldn't put up enough antennas to cover it all. So, using my inverted Vee and and Antron 99 (to take advantage of polarization of others on the higher frequencies), I can do all I need to do. I *may* not be the loudest fella on, but I DO get good reports, AND good reviews from other LDG owners.

Hope this helps.

If you insist on 50 Ohm skinny cable, get the LMR240. Loss for 15 feet will be 1.15 db. I believe HRO sells it. About the same diameter as RG59. There is also an LMR240UF, which is very flexible. The UF has slightly more loss, but at 15 feet you won't see it. $10 should get you 15 feet. We used this stuff at 2 GHz. The regular 240 has a solid center conductor, the UF is stranded. You might have trouble getting a BNC connector on the non-UF.

Dave,

I bought one a few months ago, and am very pleased. It is solidly built, hears very well indeed, and has very clear sound. Sort of the old "Super Radio" made digital, and built like a tank. I find the WX alert very handy, though if you are going to use that, it definitely wants to be run off 110V rather than batteries, since the receiver is on continuously even with the radio switched off. You can turn that feature off, if you wish. As with any specialty product, it probably is a bit pricey, but I find it well worth the cost.

>Being a loop, it
>is also somewhat immune to near-field electrostatic interference such as
>from nearby power lines (which may account for the lower noise pickup)

Dunno...I consider this to be fictional content...
They may be slightly quieter as far as corona buildup, or
charge on the antenna itself, but not any noise in the far or
near field. If a loop picks up less noise in a certain direction
vs another antenna, it's the inferior antenna in that direction.
Noise is rf, and a signal, the same as any other signal.
If you get rid of noise, you get rid of *any* signal in that
direction and angle. I also consider the magic noise reducing
qualities of the "shielded" loops to be a fairy tale also.
I've done a good bit of testing, and can see no indication that
a shielded loop is any "quieter" than a regular unshielded loop.
The shielded loop design promotes good balance. But good
balance can be had with any loop.
I guess loops are ok, and they are efficient when fed with coax,
same as a dipole, but I usually prefer dipoles on 80m.
If you run a loop for NVIS, you want it all high up in the air,
with no parts dragging towards ground. Many stick loops
in the yard, and some parts will be high, some parts low.
The current distribution is "fairly" constant around the loop,
vs max on the dipole being at the feed point. So you have
more chances of increased ground and clutter loss with the
loops in many cases. I prefer the dipoles and inv vees because
the maximum current point is up high at the apex, and the
ends of the wires, which may droop lower, are voltage nodes.
I'd rather have the bulk of my radiation high up in the air,
rather than spread helter skelter around the yard area.
Often the dipole will outperform such a draggy loop...
But if all the loop is high and well supported, they can
be worthwhile. But still more work for little if any real
increase in performance vs the dipole.

Does anybody have a copy of K1BQT's article from the Summer 1997 issue
>of Communications Quarterly,

He used to hang around here, but haven't seen him in ages...
Seems like I heard he was doing some work for cushcraft,
or someone, but I may be thinking of someone else...
He's the only person on this newsgroup I've actually talked
to on the air...:/ Was on 10m, and I was using a 1/2 wave
vertical at 20 ft...Yakked for a good while.. I do hear W8JI
on 160m loads of times, but I've never actually called him.
He's always busy working all that far off dx, and I hate to
bug him.... :/ Heck, most the time, I can't even hear the
stuff he works...It's fairly disgusting... :(He works mostly
CW.

Listen, these nice guys are all BS'ing you. Remember that cable is
rated in dB/1,000ft, so that with only 15 of cable -- ANY -- will be
about the same. You will probably have more loss in the connectors!

A*s*i*m*o*v

Huh? All my charts list loss per one hundred feet...however, unless he
needs every last bit of signal, 15 feet of RG-58 would be OK...see:
http://bwcecom.belden.com/Catalog/TechInfo/Coax%20Electrical%20Characteristics.pdf

There ain't such no thing as a low loss thin cable! not for high frequencies, anyway! what experience teaches is to put up the thickest line you can within the closest reach of the antenna, and use the absolute minimum of thin, flexible cable from there to the antenna itself. in any case you need good connectors at these frequencies so the additional price is not a real killer.
there's no way to dodge the physics at these frequencies. try to fish out reel ends of CATV cables from your local comapny. usually they're glad to give it away, if you rid them from it. I even got e afew connectors for my pain. in any case you need to match the antenna to the cable, so why not at 75 ohms instead of 50?

You might call and ask if they've improved the digital display. I have
a plain CCRadio, and the display only lasted about two years before it
quit showing numbers and letters. Fortunately, I put all of my
favorite stations in memory before the radio went blind.

I asked about their repairing the display, and they want a minimum of
$49.95 plus shipping both ways.

Otherwise it is a good radio, altho' I'm not sure it's really much
better a DX-type radio than others. Still, it does have the 8-inch
ferrite antenna, plus screws where you can attach an external AM
antenna.

My much cheaper GE SuperRadio has about the same receiving
capabilities, but with analog tuning, and a better audio setup; it's
like a little mono boombox.

When I lived in AZ, where the wind blew almost all the time
and the humidity was very low, particles in the wind would
deposit their charges on my dipole causing an extreme amount
of noise and sometimes even arcing. I hear dry snow can do
the same thing. I was trying out a 4:1 voltage balun one day
and noticed that particular noise source had gone away since
the balun was a DC short and bled off the charges. A later
loop also didn't have the problem. An RF choke or high-ohm
resistor across the dipole feedpoint will also cure the
problem.

I bought one hoping to receive 10kw WTAW clearly at night
from 30 miles away. It's a nice radio but didn't solve
that midnight reception problem. My Grundig Yacht Boy 400
receives just as well as the CCRadio Plus.

Source record: 67756

A SOLID POLYETHELINE COAXIAL LINE :-

Length = 5 metres (15 feet).
Outer conductor diameter = 25 mm (1 inch).
Inner conductor diameter = 7 mm (1/3 inch).
Impedance = 50 ohms.
Velocity factor = 0.665

At 900 MHz, it has an overall matched loss of about 0.8 decibels. With an SWR of 2:1 loss may increase to 1 dB.

The above figures will give you some idea of the sort of stuff you are looking for. Halve the diameters and roughly double the loss.

For any other dimensions download program COAXPAIR from website below. If you have any cable of unknown characteristics lying around doing nothing, then have a sensible guess at dimensions and just insert data into the program. It is very easy to use.

The program itself, from audio frequencies up to the GHz range, is generally at least as accurate as cable dimensions can be measured using ordinary engineering instruments. It is of professional grade, usable by cable designers and workers in the field of resonant transmission lines for impedance-matching purposes. One useful program output is the input impedance and SWR of any coaxial line, of any length, for any terminating impedance at any frequency. It is necessary to know the line's velocity factor which for solid polyethylene is always 0.66

Other types of line are similarly covered by other programs available from the website.

But for your particular application, download program COAXPAIR.

Isn't our old friend WTAW on streaming audio as well? I think I recall hearing that it is. As a thought to the original poster, perhaps the stations he is seeking are on streaming audio over the web as well.

Incidentally, I'd love to be able to get KMVL-AM in Madisonville where you are, at the in-town family home site in College Station, at night, chuckle. But at night on 1220 when KMVL-AM is at 3 watts, that's even a few DB worse than your choice for 10KW, grin.

WTAW advertises 10kw but may run at reduced power at night.
That might be part of the problem. And I could switch over
to KMVL but music doesn't put me to sleep as fast as Art
Bell. :-)

Cec, in this little country we don't seem to suffer from static from dust or other dry storms. Rather rarely, when a thunderstorm is in the vicinity, I have experienced rain-static which occurs only during a heavy 'tropical' downpour. At such times I am inclined to disconnect the antenna, anyway, to avoid damage due to a direct lightning strike on the antenna or house. The S-meter may rise to S-10 or S-11 for a few minutes but this extreme occurs only once every few years. I have never experienced static due to dry snow. I have only once experienced static on a nice warm day with a completely blue sky and this lasted only for half an hour. Never figured out why.

Using a high value resistor or choke to ground the antenna doesn't have any effect on S-meter noise level. I would not expect it to.

I cannot see how loop antennas are less susceptible to static except that their smaller size may have a smaller catchment area for particles or raindrops.

Could you briefly describe what happens to the S-meter on the 160, 80 and 40 meter bands when severe static occurs in Texas, or any other States, and how frequently static weather conditions occur strong enough to temporally put one off the air?

Reg.

Hi Charlie,
I have owned mine since 2003. I have used it with
an AL-811 on an 80m loop
and an 160-10m "Cobra Ulyra-lite" antenna. It worked very good on the
loop,BUT I had some
matching problems at 160m. I finally got it all working by adjusting
the feedline lenths on that
antenna. The ant. comes with 100ft. of ladderline,which I then
connected to the Radioworks
"remote Balun"/ 4 to 1,and the to 20ft. of rg-213. It wouldn't tune
there! On 160m, at about
1930mhz, it just quit! I had to change the LENTH OF THE COAX to 50ft.
! ! I don't know
why,but it works!! The TUNER.....well, I have to say that it
makes a lot of noise,BUT
It works great,and i would buy it again!!!

Good "radioing" my fellow ham,

RayN KB1-GHH

Just bring the two 450-ohm wires close together for a few inches and
bring them into the shack through a small, single, insulated hole in
the wall or window frame.

Once inside the shack you can do what you like with it for the few
feet between the hole in the wall and the tuner / transmitter.

On my IC-745 in AZ, the coax connector would arc many
times at the transceiver about once a month during late
summer. It pinned the S-meter but didn't seem to
damage the IC-745. It arced whether the IC-745 was
on or off. A 4:1 voltage balun cured that particular
arcing problem although it generated other problems.
The PL-239 coax connectors must arc around 300 volts
or so.

What is the feedpoint impedance? Single band?

> Getting the 450 line into the shack!!

If the feedpoint impedance is around 50 ohms and it
is single band, feed it with N*1/2WL of ladder-line
through a 1:1 current/choke balun. Coax can be run
from the balun into the house.

Owen,
I believe you are mistaken. The carrier frequency is given. It will be measured, in Newington, against either a cesium or rubidium standard (don't remember which), but I don't know if it will actually be _controlled_ by the standard.. It is only the audio tone which is the unknown.

> comments?
>
> Dave Pitzer

Hello Dave .... I would not reccommend the CC radio for a number of reasons. First I find that it is susceptable to noise ...don't ask me why ...I am not an engineer ..... The damm beeping of this thing on band change is unnecessary and irritating. It does not have the ability , with the internal antenna, to pull stations apart and out of the mud ... IMHO. The display could use a little more contrast for my back none of life eyesight. I live about 30 miles from Pittsburgh and have difficulty with AM stations from there at night ....which was the main reason I got the radio. The small Toshiba F 11 I bought years ago is a better AM receiver. I don't have any experience with the GE super radio but I know fellows that like them. Reception probably would be better with a turnable loop but I have other projects to work on before that happens. The expense - performance curve is way off ....again IMHO.

Hopefully you will be more satisfied than I am if you go this route.

Take care ..... Tom Popovic Belle Vernon PA

OK, I found that QEX after much fuming and searching, under some recipes, bills and phone books in the kitchen ...

Giessinger doesn't refer to Day's work. Among several references is one to a work by Robert Dick in the Jan/Feb 1999 issue of QEX.

I won't try to paraphrase extensively, since I don't think I understand the technique well enough to do it properly. It involves analyzing vowel sounds, which have a fundamental and harmonics of predictable relative amplitudes. I suppose you find the harmonic peaks and note the error in their frequency relationship caused by mis-tuning, and there you go. Sounds simple, if you don't have to actually do it. ;^)

I can see where it would be pretty straightforward (relatively) with music, but doing this with voice is impressive to me.

Apparently similar techniques are now being used in high end rigs like the IC-7800.

Steve Muldoon [N8KOM]

Roelof Bakker's "PA0RDT Mini-Whip".
http://beaconworld.org.uk/images1/alspics/miniwhiplarge.jpg

I have also added a new antenna recently, the amazing
little "mini-whip" designed and developed by fellow
Dutch NDB Enthusiast Roelof Bakker, PA0RDT.

This small 'active whip' is not much longer than my pen,
and works very well from its perch at the top of my bird
feeding station in my back garden.

If space is a problem at your QTH, or you are planning
some outdoor operating in the near future, one of these
impressive little devices might be just what you are
looking for.

NOTE - There seems to be few references to the PA0RDT
"Mini-Whip" Active Antenna.

> through the wall then mid-air it 5 feet to the tuner....??

I've never used notched-plastic, looks-like-wide-TV 450 line, but I have used true "open wire" kind (two parallel wires with 1" separation and little insulators every six inches), and to get that through a wall I used two ceramic "tubes" from old "knob and tube" house wiring by drilling two holes with 1" separation thru the wall (with a slight downward slant so water runs out), cut the 450 line at the appropriate place, remove one insulator (to give a little working room), thread wires thru insulators, and solder the line back together inside the house....

A RELATED QUESTION: what is(are) the difference(s) between the two kinds of 450-ohm line? I suspect the velocity of the true open-wire kind is a little higher and loss and moisture effects are a little lower than for the partially-covered-in-plastic line?

Bill,
You can do it either way, just not that critical. Or,
as Reg suggested, or Cecil. Or, put a board in a close window,
drill a couple of holes in it about an inch apart and run
'connection' wires through from ourside/inside (or a couple
of bolts).
I'm sure you'll get other suggestions...
'Doc

Date: 2005-11-15 13:40:35 UTC
From: amdx <amdx@worldnet.att.net>
Message-ID: <a9d60$4379e54e$18d64e2f$22584@KNOLOGY.NET>
Source record: 67626

The recent CCrane thread got me to wondering again.
What would go into building a good system for receiving
BCB A.M. radio?
A complete system, starting with a directional antenna,
(loop, flag, etc.) A system to seperate stations on the same
frequency. Building a strong front end. Good audio.
Just looking for a discussion regarding design of a great
BCB radio.

Mike

3480. Hi-Fi tuner aerial connection query.

Newsgroup: rec.radio.amateur.antenna

Hi
I would like to connect my hi-fi's tuner to my TV's communial aerial
socket on the wall with the aid of some sort of coaxial splitter, is
this possible? On the rear of the hi-fi are the aerial connectors which
appear to accept strands of exposed wire by pressing and releasing a
small lever. The five connections are split between 300ohm, 75ohm and
AM. Whats the best way to get a decent reception from the tuner?
Thanks for any advice.
Johno

I'll try the long wire antenna attached to the coax center conductor. I can put around 60ft of #12ga single conductor insulated wire. Should this be at right angles to the stations I want to receive or parallel? What do I do with the shield on the coax?

How about doing it in software with a simple direct conversion receiver
and I/Q outputs going into your PC's sound card line ins? Lots of
provision for DSP filtering, lots of available audio b/w etc...

Cheers Bob VK2YQA

Getting the standard changed to SSB would be a great start, but it'll
never happen.

Even better would be to eliminate all HF broadcasting and move it to UHF FM.
That "might" happen, but not soon.

> Thanks for any advice.

You can get passive splitters that are fairly good devices. Try any radio-
TV parts store for one of those. Connect one output to your regular TV's
antenna connection and the other to the 75ohm input on your tuner. This
will get you any FM signals that are being carried on the communal system.
For AM, you're better off just attaching as long a piece of wire as you
can, unless you want to get into special active antennas.

Mike wrote:
"Just looking for a discussion regarding fesign of a great BCB radio."

It has already been done. The SCR 274 N or ARC-5 series included a receiver which covered most of the AM broadcast band. With a wire connected to its antenna post, a unique signal appears every 10 KHz Across the dial. All that`s needed is transistorization. I used one of the originals with a 12-V dynamotor as a a car radio for years.

Best regards, Richard Harrison, KB5WZI

Ok, how about the Tayloe detector, it has a strong front end and I and Q
outputs.
Anyway to use this to eliminate stations on the same freq. Maybe two
antennas and two
detectors phased or computer manipulated?

My 600 ohm open line comes in through a horizontally sliding basement
window.
I simply use fiberglass insulation on either side of the line and bring it
in with the
one conductor above the other. Then I use the sliding window to put
compression
on the insulation.

Steve,

I have been using a W9INN antenna system for years and I don't think Bill (w9inn now SK) ever sold an antenna with a balun. His antennas came with a balun looking device that was just a center insulator.

FYI, I have my W9INN 80/40 dipole mounted on a 1 foot stand off with cord and pulley arrangement for easy adjustments. I modified the antenna by adding extra wire sets for the WARC bands and it now should be called a fan dipole in a Vee configuration.

It has always performed well and we are all going to miss Bill, W9INN. I recalled years ago working Bill on 40 meters and he said I was the first person he had ever really worked on the air using one of his antennas.

Thanks!

Looks like a groundmounted vertical is the way to go for low-angle DX.
I'll watch out for the lightning as well!

Now that we have heard all the benefits of various loop antennas, I have a question about the physical part of the antenna. I am planning on erecting an 80 meter or perhaps 160 meter square loop antenna. The question is how have you fixed the corners of your loop antenna? Can the antenna wire move in the insulator so as to equalize the force on each side? Or is the insulator in the corner fastened tightly to the antenna wire? Also, what type of insulators are your using in the corners? Ceramic compression? Glass, Other type ceramic? Anyone using plastic insulators?

Hi Paul, Make the loop out of insulated stranded #14 wire from Home Depot, Lowes ect.. The corners can be of UV resistant rope with a loop in it. The wire will slide in the rope loop. Should handle a KW and stay up a long time. Don't need glass, ceramic or any other type insulator.

Hi Dave,
I believe the resistor should not be inductive and it should have at
least 30% of the transmission power therefore, for 1500 Watts it should
be of at least 500 Watts.
I build the balun for this antenna (andthe antenna) but I believe in
your country is not difficult to acquire it.
I hope it can help you.
VY 73s,
Silva.

Dont know Mike

I would suspect by itself I/Q detection/demod wouldnt help in a
situation where AM stations are using the exact same frequency.

Two antennas/RX detect systems could certainly be used if you can get a
usable phase diff between stations and use that for phase cancellation.
(ie not an I/Q RX as such) Could even do that in software and be very
specific as to what phase diff range is cancelled. You'd have to sample
at RF rather than AF though which makes the project more $/complicated.

You could also DSP filter based on audio content. That would be a real
difficult one!

Directive antenna?

Cheers Bob

3505. feedlines and strange intereactions

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-16 16:19:33 UTC
From: Paladin <kb1ghh@hotmail.com>
Message-ID: <1132157973.945787.48940@g14g2000cwa.googlegroups.com>
Source record: 67652

Hi Group,
Recently,I put up a linear-loaded dipole for
160-10m. It's ladderline,4/1 balun,
to coax,to good brand auto-tuner. It's supposed to work with 100ft.
of ladderline,BUT....
It wouldn't cover the lower portions of 160. To get this antenna to
work on 160, I had to cut
off 20ft. of ladderline, AND also use a 50ft. piece of coax! I tried
using only 20ft. of coax
because that's all I need to get to my tuner,but it didn't work! ! !
What happened here, to me,goes against almost everything
that I learned about
feedlines! Change the lenth of coax ? The 100ft. of ladderline
was at least 1/4 wavelenth
of 160,right? The feedpoint is at 55ft. on a tower (about 2ft.
away the tower) the ends are
in an inverted-"V" at about 15ft. above the ground. I do have a 80m/
272ft. loop also in the
1/8 of an acre back yard. Some small 2 & 6m beams hung of the
tower,not near enough to
cause intereaction. WHY AM I HAVING such a hard time getting this
antenna to cover
this bandspread ??? Also, IF I have a multi-band antenna,feed with
ladderline ONLY, to
a very good tuner; Why are the signals that I rercieve on the higher
bands,(160-10m)
usually SO LOW in strength ? Ex: On 160 or 80,the antennas s-meter
usually reads
over s-9 at night,o.k. Now, the same antenna on 10m or 20m during
the day are reading
very low; mostly around 3's and 4's. I guess that I really don't
think that calling THESE
antennas "a 160-10m antenna" or my Loop a 80-10m antenna! ! I've
had both antennas
up now for at least a month. Signals for 20m-10m need a different
antenna, In my
opinion. BUT, I'm still trying to understand exactly just WHAT
antennas can or cannot
do for me.
73's,and keep
radio-active,

Paladin

Paul,
It really doesn't matter to much how you prepare or fix the corners. I have used free floating and fastened down tight. If they are in the trees sooner of later the wire will snap regardless of how you have the corners prepared. The alpha-delta cin insulator from Radio Works $1.50 are very good one to consider using.

I don't know much about these antennas but I have a friend in Colorado who has one and we often talk on 20 or 40 meters. He has only 100 watts output and he puts a strong signal into Alabama. It certainly seems to work for him. I have a Carolina Windom and I believe his Isotron performs better than my windom.

Due, no doubt, to radiation from his feedline. If you both
replaced the vertical section of your feedline with a good
ground-plane vertical, it might improve even more.

Hi Paul and the group,

I let my corners float and all I use are pvc 1/2 or 3/4 pipe 90 deg. elbows with dacron rope tied to around them then flug over a tree. Been using this method for years. No pulleys or extra fancy methods just rope and a elbow, this way I can move the antenna around if I choose to change my feed point at any time. Also allows for the stresses to even themselves out between the trees depending on how the wind blows. Although one tree is a very small sapling that stands about 40 feet high and the other three trees can pull it via the antenna wire with no great effort at all. Also have enough slack in the antenna to allow for rapid wind changes.
Everyone has a different method and most are very good and serve the purpose they were intended to, one persons idea may not work in another area, but to each his own method works otherwise there would be a lot of trial and error going on, hi hi. Been there done that and got the hat to show for it to.
I'm fortunate in my area as I don't get much wind at all, although I have used a similar method on the west coast of Vancouver Island with weighted milk jugs instead of tying off the support line for two of the four support lines.

3513. Nature of "ground" beneath my house?

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-16 19:24:39 UTC
From: mcalhoun@ksu.edu
Message-ID: <dlg11n$qf5@unix1.cc.ksu.edu>
Source record: 67661

What kind of "ground" should I use to EZNEC-model a flat-top dipole antenna
of which one side will be about 7 feet above and parallel to the peak of
my house roof and the other half will be about 30 feet above the yard.

My house is a story-and-a-half (the usual attic was a dormitory for my
long-gone kids) over a full basement (which just happens to have both
a Ufer ground in the basement-wall footings and a "ring ground" around
the outside and at the level of the footings). Thus most of one-half
of the antenna will be over the usual Kansas soil (about a foot of fertile
stuff above many feet of more clay-like stuff) while the other half will
be above the roof above the attic/dormitory above the ground floor above
the basement above the footings.

So will this be a "good", "bad", "average", or ??? ground for EZNEC-
modeling purposes?

Source record: 67660

I am beginning my planning and construction of a small loop antenna for 80 meters. The loop will be constructed out of 3/4" copper pipe, octagon shaped, and have a perimeter of 72 feet. The plane of the loop will be vertical and will be resonated by a variable capacitor in series with the top pipe section. The voltage and current through the capacitor have very large values.

See http://tinyurl.com/bwobb for more information. Any comments, thoughts, and advice will be greatly appreciated.

Bill;

The best antenna for you is the antenna that works. I use a B&W folded dipole antenna daily. It does the job I need it to do. There are those that deride it as a "lossy dummy load". What it is is an antenna that dumps any excess energy into a 600 ohm resistor. The excess energy is that which is reflected back into the finals by any other antenna. It allows me to QSY and be tuned to any frequency I wish to use. In that I use NTIA frequencies in addition to Ham frequencies this it the best antenna for my use. As I said it works.

Dave;

The only source of resistors and baluns that I have found suitable for making a B&W antenna is B&W. The terminating resistor is 600 ohms non-inductive i.e. carbon. The balun is 12 to 1 i.e. 600:50.

If you do find instructions on making the balun please let me know. I use my B&W BWD-90 daily and it does the job I want it to do. I need broad band instant QSY for my radio.

3517. Self capacitance of solenoid coils

COPIED FROM ANOTHER NEWSGROUP

> I see you are a follower of Medhurst.
>
> You might like
> http://www.eagleware.com/pdf/apps/2020_FiltOscUsingSolenoid.pdf
>
> Andy, M1EBV
==========

Andy,

Thanks for pointing me towards the above document.

I've never heard of Medhurst. Or anybody else who might have messed about with an arithmetical treatment of the subject. I've never bothered to look.

I can't understand all the details (the paper is not very well written) but I gave the paper a couple of speedreads.

It's interesting because it treats a solenoid as a transmission line.

A few years back I evolved explicit formulae for calculating the self-capacitance and self-resonant frequency of single-layer, solenoid coils. Such coils are fairly common. They are used, for example, as RF chokes and, when wound with coaxial cable, as chokes in coaxial transmission lines. Sometimes they are just a hank of a few turns of coaxial cable. Apart from their connecting wires they are, in effect, isolated in space. Long solenoids also form helically wound vertical antennas which can be top-loaded with a rod. Or horizontal, short, continuously loaded dipoles where the resonant frequency is required to be predictable in advance of construction.

With chokes it is required to calculate the band of frequencies over which the impedance exceeds a fairly high given value.

My formulae are based on transmission lines with conductor length and diameter corresponding to length and diameter of the solenoid. I discovered this by analysis of the problem. (The author of the article discovered it by accident when making measurements.) Provided the number of turns is greater than 5 or 6, even with close-spaced turns, the capacitance between turns can be ignored. Very thin wire compared with wire spacing does decrease overall capacitance but not because wire-to-wire capacitance is less.

As a check on the formula, if the wire is stretched out to be an exceedingly loose helix, then the resonant frequency becomes that of a

straight length of wire - the wire is just a half-wavelength dipole and its resonant frequency coincides with the formula.

Several of my programs use the formula which incorporates an inverse hyperbolic function. It always struck me as being incongruous to use such complicated functions for such a simple matter of calculating such a very small, inconspicuous capacitance. See programs SELFRES3, SOLNOID3, HELICAL3. There are other programs in which self-capacitance matters but the program user is unaware of it. What use could he make of it if values were displayed?

An Autic Antenna Analyser can be used to measure the self-resonant frequency of a solenoid coil very accurately. Just place a 1 or 2-turn link-coupling around the CENTRE of the coil without any other connections. Connect the coil to the meter via an 18-inch length of loosely-twisted pair of wires. Suspend the coil in free-space using only the twisted pair. On the impedance magnitude range, tune the analyser for a VERY sharp rise in impedance - and there you have it. Maximum impedance will be several hundred ohms. Q will be very igh - it is easy to miss resonance. So much for old-wives tales about poor Q at self-resonance. You may notice a sharp null in the meter reading at a very slightly higher frequency which is due to a series-resonance in conjunction with the twisted-pair and the meter itself. If you can't detect a null, don't worry about it.

This method works (I know of no other) with short fat loading coils, with 160-meter helical antennas 6 feet long with 1500 turns, and with coaxial chokes using a hank of a dozen turns, 8 inches in diameter. It fails when the coil's resonant frequency exceeds the range of the meter.

By the way, the self-capacitance of coils depends on their close environment. It can jump about all over the place and change when long connecting leads are soldered on. My formula applies to a coil in free-space as the sensible starting point. I could derive an approxima te formula for your toroidal coils, they are only bent transmission lines, but at the age of 80 I don't wish to expend any further time on the subject. <smiley>

Source record: 67665

Just call it "poor" ground. But try them all.

My guess is that it will make very little difference in performance as calculated by EZNEC whatever you call it.

Horizontal or sloping dipoles are insenstive to what's underneath them. Radiating efficiency will be in the right ballpark.

The structure, position and height of your house will have a much greater but indeterminate effect on radiation pattern and you cannot model your house using EZNEC. Even nearby neighbor's houses will have some effect. But you will never know what these effects are compared with the ideal pattern as presented by EZNEC.

Antenna height above what's underneath is the most important parameter.

In all probability, you will get around and about very well. Many amateurs do very nicely with even more peculiar antenna systems.

Reg.

David G. Nagel wrote:
> The excess energy is
> that which is reflected back into the finals by any other antenna.

Sorry, in a tuned system, the "excess energy" is re-reflected
back toward the antenna at the match point. Here's an example:

100w XMTR--50 ohm coax--+--1/2WL of 300 ohm twinlead--50 ohm antenna

More than half the forward power is reflected from the antenna
but it is turned around and re-reflected back toward the antenna
at the coax/twinlead junction at point '+'. The reflected energy
reaching the finals is ZERO!

Reflected energy, per se, is not bad. Reflected energy that is
allowed to reach the finals is bad. In most systems, an antenna
tuner solves the problem.

I've got about 50 of those 50w suckers in my junk box. They
don't have to be carbon. If one reverses the coil direction
of the resistance wire at mid-point in a wire-wound resistor,
the inductance is minimumized over a certain range of frequencies.
That's what the military often does.

If you keep water off the PVC, all your problems will be mechanical.
A couple of years in the Phoenix sun usually turns PVC into powder.

Looks like I have an opportunity to purchase a Butternut HF6VX 80-10
vertical with the CPK counterpoise for maybe $340 for the whole thing.
Seem like a reasonable thing to do? Decent antenna? Otherwise I have
my 80 meter full wave loop at about 50 feet. I'm assuming the vertical
would outperform the loop for DX on 75 and 40 meter bands.

That loop is detailed in chapter 5 of the ARRL Antenna Book (19th
ed.). Might be worth getting the book if you're going to build it.

Silva;

No reason why your plan should not work. It might require differend
spacing but that is what amateur radios if for: experimentation.
I will give it a try. Where did you get your balun or how did you make
it? Is there a web page showing how?

> modeling purposes?

The short answer is that it doesn't matter.

I do recommend using "Real, High Accuracy" ground for all models unless it's necessary to make a zero-resistance connection to the ground plane.

When using "high accuracy" ground, the ground quality is used by the program for two purposes: 1. To determine the antenna impedance and currents, and 2. To calculate the pattern, which depends on ground reflections. The former doesn't make much difference if the antenna is more than about 0.1 or 0.2 wavelength high. The latter takes place (except for very high angle signals) well beyond your house or other nearby objects, and for horizontally polarized antennas doesn't make much difference anyway (again except for high angle signals).

Whatever effect your house will have on the antenna, you won't be able to effectively model it. It will be chiefly due to the conductors in the house -- wiring, pipes, rain gutters, etc. -- and it's just about impossible to know enough about them to model them decently. Fortunately, they're unlikely to have much of an effect unless something happens to be nearly self-resonant. If that happens, you're likely to know about it via other means (e.g., TVI or other RFI, "hot" conductors or appliances when transmitting, or even lights that go on when you transmit), and will be wanting to spoil the resonance rather than simply modeling the offending conductor.

No. I have a four-square array in which each element is a quarter wavelength at 40 meters, 1-1/4" diameter at the bottom, and clamped to an 8 foot galvanized steel chain link fence line pole driven 4 feet into the ground. The antenna and 4 feet of protruding post are spaced 1/4" by slices of thick wall PVC conduit, and clamped with muffler clamps. The protruding pipe is connected to the ground system. They've been up for about 20 years. The only effect of the pipe on 40 is to add a bit of shunt C at the base of the antenna which lowers the self-resonant frequency a bit. The effect is considerably more pronounced at higher frequencies where the antenna base impedance is higher.

Hi John,

The bottom would seem to be far more accessible and you should loop
feed the entire antenna (a loop inside the loop, that is) - Reg has
many times pointed out this matter of simplicity solves many
headaches.

Hi Chuck,

The bottom one or two bands of multiband verticals tend to be
disappointing in performance - or so report many to this forum.

If you do get it, don't take the loop down.

Dunno...Sounds like it was working to me.

> I did the next logical step and tryied magnetic loop for 80, reciving
>only, indoors.

What are you trying to hear? Sounds kinda illogical to me, if
you are working NVIS... :/

>What would you do in this situation? Loop, magnetic loop, dipole,
short
>beverage perhaps???

I'd go back to what was working. The dipole. If the noise is from the
shack,
the use of baluns or chokes to decouple the feedline can be used.
But I think the noise you heard was the normal atmospheric noise you
would hear on 80m. I often get S 8-9 noise levels on 75 until winter
really kicks in. It's normal. Noise is normal. It's RF. I'd be more
worried
about *not* hearing any noise, than I would be hearing it.
Also, don't lay the antenna on the roof. The higher you can get away
from
it, the better. A loop will be no better than the dipole in general.
Both are about equally efficient if fed with coax. But the loop is
more wire, and more work.. :(
On 75m NVIS, almost all signals will be over the noise, unless you
have a local T storm brewing...Noise is not an issue...Well, not to the

ones with decent antennas... To one using a full size dipole fed with
coax, even 100w is plenty to get over 95% of the noise you will run
into. An S 9 noise level is no big deal if the signals are 20-40 over
9.
And this is the norm.. Only the guys running funky gimmick antennas
will be hard to hear.. :/
There are some weird ideas around about noise... Almost as many
fairy tales as with grounds and shielded loops.. :) No joke.
Good antennas pick up noise. That is what they are designed to do.
After all, noise is just rf like any other signal. If the antenna is
"low"
noise, that usually means it's half crippled in some way, unless the
noise is ingress from the shack. :/ And thats from the lack of a balun,

choke, etc at the feedpoint. Easily cured. Just rolling a few turns of coax into a choke can reduce much of it. But like I say, I think your noise was normal band noise. Listen now, after the cold front blew through the country. I bet it's a tad quieter on that dipole now.

3535. Emoto Rotators

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-17 10:04:06 UTC
From: fred@nurk.com
Message-ID: <437c5597$0$9984$5a62ac22@per-qv1-newsreader-01.iinet.net.au>
Source record: 67682

Hi All,
I have been offered an unused Emoto 1103 (or 1102 - not sure as no external markings) at what appears to be a very reasonable price. The only problem is that it does not come with a control unit.
I have searched the 'net high and low for information but to no avail.
So - my choices seem to be:
1. Acquire a circuit of the rotator so that I may make my own control unit.
2. Purchase a suitable control unit (the local agent in Australia is unable to supply same)
3.Sell the rotator on behalf of the original vendor (a friend, who would be more than happy for me to do so)
4.Forget the whole thing and stick to bits of wire stuck up the nearest tree :)

Any help or advice will treated with the respect it deserves!
Cheers

Hi Richard,

Yes, I've been very pleased with the loop, worked about 30 or 40 countries in the last year on it, mostly on 20 and 18 meters, but it does well on 40 as well, being fed with balanced line. According to EZNEC it does well on 15 and 10, but with the current sunspot cycle who knows. With the all-too-few openings on 6 meters this summer, I did have some pretty good luck, though I could tell the yagis could hear quite a bit more than I could.

Chuck

3538. 'modified' skyloop antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-17 12:59:19 UTC
From: HankG <hank@invalid.com>
Message-ID: <dLSdncm2mdw44-HeRVn-vQ@comcast.com>
Source record: 67685

Due to a small and irregularly shaped lot, I am using Cliff Donley's Hot Kiss [(see message 2471 Yahoo RX-320 group) (a 33 foot folded dipole w/7 foot matching stub, all made of 300 ohm twinlead, fed with 75 ohm coax through a standard tv balun)] antenna.

The antenna performs well for HF (receive only). As I also like to listen to MW and LW broadcasts, I used a long wire (directly connected), passed out of a window (I'm on the second floor), and run around the house perimeter at ground level. The total length about 200 feet. The antenna works but is rather noisy.

I considered installing a skyloop in my attic, but the total length would only be about 120 feet.

I am asking the resident experts to comment on this idea:
The plan is to run a loop made from 4-conductor telephone station wire around the attic floor, connecting each end-of wire to a wire of a different color, therefore amounting to one long wire (about 480 feet) encircling my attic in four turns. A higher number of conductors could be used if practical. Also, a matching transformer and coax are options.

As mentioned, this would be for 'receive only'. Would a tuner be necessary? What would be an optimal length for the loop?

O.K., let me have it. Thanks for any suggestions.

HankG

It seems to me that it's a lot easier, from a mechanical standpoint, to use a simple gamma feed (without a capacitor) at the bottom of the loop. This is a one band antenna, so finding an optimum match should not be that difficult. If I feed the loop at the bottom with a gamma match, then symmetry requires the capacitor to be at the top of the loop.

However, if using a second one-fifth sized loop as the feed loop allows me to mount the capacitor at the bottom, then this type of design might become attractive. It is not clear to me how easy it would be to keep the relative positions of the two loops fixed.

Thanks for the input so far. Maplins is a similar store in the UK to
Radio Shacks. So just to confirm, I have a two stranded aerial wire.
One end of the aerial wire I am going to connect the two stands to the
tuners 75ohm aerial sockets. What do I do with the two strands of wire
at the other end of the aerial wire? As I have said I am a complete
novice here but from this response this probably does not need
repeating. Johno

Connect to the splitter. The easiest thing would be to draw a diagram
of what you have, take it to Maplins, and they can pick out a splitter
that will work, along with any cables or plug adaptors you might need.
It's sorta hard to describe all this in text :-)

If it is a used antenna, that seems overpriced. You can buy a new
one for less than that (without the CPK). You can easily make your own
radials for much cheaper.

I've used HF6V's at several qth's. It's a good antenna on 40 if you
have enough radials. On 80 it's not that great. But it will be useful in
addition to the loop.

True --- but I would go with the omni directional anyway, for the same
reasons that you mentioned.

Sea action will move the antenna about in the xy plane as well as up and
down. There is more than simple up and down bobbing going on here.
There would be no guarantee that the forward lobe of a directional
antenna would be pointing towards the receiving antenna.

Yes, the lowest bands don't work so well on the Butternut, but you should be able to find a used one for considerably less than that price. (I've been seeing them go used for $75-$125).

I've had a Butternut HF6V on my roof for some years now, which wound up being about 15 feet above the ground, with one radial for 80M, and about four radials for 40-Meters (and the higher bands). I've had this antenna at five different locations over the years.
Using it, I've made 5BDXCC (plus 30M DXCC). I only have about 185 countries on 80-Meters with it, and only about 260 countries on 40-Meters with it. Then there's 160-Meters - only about 40 countries so far.

Some day, I hope to have a real antenna for the lower bands. Right now, the Butternut is down since there's some building construction going on at my home, and all I have up now is an 80-Meter Inverted-Vee, which is now my "all band" antenna. It's up about 25 feet above ground in the center, five feet above ground on the ends, it's fed with 450-ohm ladder line. Sometimes it takes me four or five calls to get through some of the pileups! (H40 on 80-Meters, KH5 on 20M RTTY, etc. in the last week).

YMMV.....

Great picture. What happens when the guy buys gas and drives under the overhang at the filling station?

It's hard to tell from the photo, but it looks like it can be adjusted
to lay flat. Whether or not this can be done in a convenient manner is
another thing, I guess.

For only 20 Euros he'll tell you how to build one and all your questions
will be answered.

Har.

Well, I don't care who you are, at least once any normal person is going to forget and drive right up to the pump without remembering to first lower or remove the antenna.

Or is this antenna story just a way to earn some money? You have to send the guy at least 20 Euros (approx 20 USD) in order to receive (hopefully) the construtional details in March 2006...

If it is a true ham project, I don't understand why the details can not be published on a simple web page. At least the outlines.

I can make a better offer. For only $20 US, I will tell you how to
build a reduced size bridge that is only 10% of the length of what is
needed to span the river, but it will work just as well. Promise!

Right. I personally would only use such a rig under special situations
(i.e., the thing only goes on for a weekend or something.) Everyday
use is asking for trouble.

Mobile installations have their own challenges. I'd probably live with
the trade-offs and put a big old whip from front bumper to the back.
One should be able to use various tricks to electronically lengthen or
shorten the whip to tune to the range you want, right?

3560. Geophysical Indices - "at a glance" freeware

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-17 22:27:08 UTC
From: J Tabor <denews@taborsoft.com>
Message-ID: <11nq0u54rbt155@corp.supernews.com>
Source record: 67707

Greetings All,

You are invited to download and use the new version of GeoAlert-Extreme Wizard. The default download is known as QSL-ware. Which basically means freeware. <G>

The QSL-ware version has no time limit and automatically downloads and displays solar indices in a friendly - at a glance - manner.

www.taborsoft.com/gawiz/

Although many will be satisfied with the default version, advanced features are, of course, available when registered. Free 60-day trial also available.

Cheers,
Jim - KU5S

An obvious fake! Who would believe our congress passing a bill with only two pages? Bet it has more when it finally gets through.

Sounds good, though.

There are so many Moore's that I have no idea who I am kin to.
I don't look anything like Archie Moore, for instance. Outside
of London, England, the city with the most Moore's is Houston.

I distinctly recall him interviewing a guy who was discussing how, if you just thought about it hard enough, you could be telekinetic and move large boudlers around just like Luke in The Empire Strikes Back. He kept saying something like, "You can't be Jesus, you can't be Satan, but anything else you can be!"

:-)

Just because Art interviews loons doesn't mean that (1) he's one or (2) his listeners are. It's just entertainment, plain and simple...

It's kinda humorously ironic that the reason some of these "we faked the moon landing" types are so sure of themselves is because they're so ignorant or just plain downright dumb that they, personally, can't understand all the science required to pull it off. Granted, there probably is no one single person who _does_, but at least most people are savvy enough to recognize that (1) there are people smarter -- much, much smarter! -- than themselves and (2) a bunch of average people with limited skills can, while working in a well-organized effort, achieve extraordinary results that no single human ever could.

If you have luxury of space, you can construct radiator to your cordless phone base station and point it in the direction you need - you will get few dBs and this may be just enough. reflectors in order of increasing efficiency and sophistication: flat surface, corner, parabaloid.

Not to rain on your parade but home wireless phones are not permitted to have extended range antennas. They are constructed so as to prevent the addition of larger antennas. When you go looking for a new phone check the range specs. Do not take the numbers as accurate as the advertising department has the biggest say in what is printed on the box and instructions. Look for one of the more expensive phones as they will most likely be more accurate in what they say they will do. Good luck

Dave N

3573. Re: Interesting HF antenna design

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-18 05:12:40 UTC
From: nm5k@wt.net
Message-ID: <1132290760.511891.45900@f14g2000cwb.googlegroups.com>
Source record: 67720

Well, I don't care who you are, at least once any normal person is
going to
> forget and drive right up to the pump without remembering to first lower or
> remove the antenna.

That antenna is a stunted runt compared to mine.
His is 1.5 m tall. Mine is 3.3 m tall in the driving
mode, 4.2 m tall in the parked mode. On mine, the
base of the antenna is on the truck cab at about
64 inches from ground. Even in the shorter driving
mode, my antenna is over 16 ft tall to the tip.
Of course, the antenna is flexible, and the stinger
is *very* flexible, and can take most any whack.
You might forget at the gas station. Once...:/
I don't forget. I use a quick connect, and if I drive
under something, I take it off, and lay it on the roof until
I drive through.
And yes, my antenna would kick his antenna's butt too
I bet. On 80m, it would probably be ugly. I note he uses
the common "gimmick" antenna sales pitches.
If in doubt, always compare the prospective wonder toy
with other fairly useless wonder toys.
And then omit to state the ground radial
conditions, etc, etc... Of course most mobiles
beat lame ground mounted verticals. This is normal.
My mobile beats my full size dipole at 42 ft on paths
over 800 miles or so. Again, fairly normal.
He says that antenna is the most efficient
that can be built for the size. I don't believe that by just
looking at it. He wants money to show the plans. :)
Hummmmm..... :/ Sorry. No sale.
Looks like a gimmick stick designed to
lure cashflow from the gullable. . :(
MK

Source record: 67721

Or is this antenna story just a way to earn some money? You have to
send the
guy at least 20 Euros (approx 20 USD) in order to receive (hopefully)
the
construtional details in March 2006...

LOL. There are plenty of gullable suckers in the world.
Just watch. He'll have a whole boatload of them rounded
up after a while. All delivering *glowing* reports of the new
"technology". Same as the other gimmick antennas floating
around. He seems to be in the same part of the world as
another leading promoter of small gimmickry. You remember
those short ugly useless thangs that relied on feedline
current to operate? Yep, this thing is shorty's bigger bro.
Ready to rule the world of gimmick radiators. :)
Yeaaa hawwww! I'll be dumping my conventional antennas
at O-clock....:/ Of course, with the lack of free info, you
can't tell if it's a fat helical whip, oversized straight radiator
or what. Of course, this is all by design. You can't make
any money if you come right out and describe what it is,
like most normal people would do. I wonder if these plans
come with a money back warranty if one is not impressed
with the design?
MK

> the wire to the passive splitter?

Use a piece of coax. RG-59 should work for this run. Put an F-connector
on one end and just cut the other end open and split the braid from the
coax. The braid goes to the ground side of your 75 ohms and the center
conductor to the hot side. A cheap jumper and chop off the connector on
one end will do the job for you on the FM side and another one with both
ends bolted on for the TV side..

http://www.ramelectronics.net/html/rf-cable-satellite.html#splitter

The cheap {$9.99) RCA one is actually overkill for your application, I think (unless your cable has stuff on it past 1ghz).

July 1996 posting

Eric --

I don't have any satellite or direct Orion experience but I've
installed a few and they do seem to be pretty brute. Result - increased
reliability. The digital control box looks nice but again no direct
experience.
>
>The alternative is the Emoto. This appears to be a beefier version of the
>Kenpro/Yaesu rotors. But they are analog controlled (I want to run the
>rotors from a Unix box), and I have yet to see anyone in this area with
them.

I ran a small survey a week or two ago (results as yet unpublished) and
asked about the Create and Emoto rotators since I don't have any direct
experience with them. To cut to the chase, the Create was given high marks

for reliability; the Emoto was not. Both rotators suffer from mediocre parts
and service support and both use the two-piece mast clamp which can be broken
easily during installation.

I don't know if this is helpful to you or just added to the band noise.

Depends on how much you know. If the Emoto is in the same price class as the Yaesu and HyGain, it would be worth while to build your own control box. I would not try to duplicate their unit; just go for something basic with a momentary contact DPDT switch for direction, and a 0 - 1 ma meter for an indicator. If this is a 3 wire or 4 wire unit, forget about it.

Andrey;

That's correct it's not permitted. Besides the antenna's already on the
phone are optimal for the frequency.
That's correct the FCC is the parasitic body that does not permit
modifying the antenna.
That's correct I care.
That's correct. The more expensive phone, if carefully selected is the
better phone.
I hope that I am a good friend, not someone who advocates violation of
the law.

Dave N

BTW: If you can work it out a corner reflector would work.

Source record: 67578

Many years back I once had a 10m dipole about 8 feet from the house at cast-iron roof-gutter level. The Tx was in an upstairs bedroom. The short coaxial line to the dipole went through a hole in the bedroom wooden window frame.

Sunspots were at their best. On completion of the installation, much to my surprise, I worked my very first Australian (in the antipodes from Birmingham) and completed the log entry in exceptionally neat handwriting.

I then went downstairs and reported my conversation with Bill in Adelaide to my XYL. All she had to say was a brief "Your dinner's gone cold.". So much for her deflating enthusiasm!

But the most extrordinary thing about the episode was the fact that the bedroom 60-watt light bulb (admittedly a temporary arrangement) came on more strongly when the key was UP and went more dim when the key was DOWN.

I was running 100 watts from a Kenwood TS-520. The bedroom light was not being run from the 240-volt power wiring to the TS-520. After years of thinking about it, I have never found an entirely satisfactory explanation.

Cecil,
I do not know how to use such programs. I'm a "late"
bloomer,in computor terms.
I guess that I'm stuck with trial and error until I find a way to
shorten my feedline in the
same way that the antenna builder did in shortening the elements of
the linear-loaded
dipole. Long sentence,huh?
Paladin
The elements are 70ft. long each,BUT the electrical lenth IS really
210ft. per side.
I know that 100ft. of 450 ladderline didn't work.

Reg;

Reminds me of my first contact using an 11 meter J-pole antenna that I made. It was only about 40 miles using 5 watts input AM. Not much by your achievement but to me at the time I thought it was wonderful.

As to you lamp dimming, I do not know what the wiring capacity of you house was but the transmitter was being fed by the same mains drop from the street as the lamp. That is, IMO, the most likely cause of the dimming. Just my guess.

Cec, You should realise it's a waste of time pointing people towards
computer programs which require a 6-weeks full-time training course to
understand what its all about. And which they don't possess anyway.

Especially when a few sentences of plain English can provide an
adequate explanation to the enquirer.

Regards, Reg.

==========
Dave,

The mains supply from the road was capable of 50 kilowatts without excessive volts drop. For a few years it was used for electric cookers, several 3-bar central heating radiators, etc., without problems. Far more than the TS-520 with an RF power output of 100 watts.

There may been something very peculiar with the 60-watt bedroom filament lamp which caused it to cool off when both RF plus 50Hz power currents flowed through it. I didn't try another bulb.

There may have been incorrect house wiring such that the only power point in the bedroom, used for the transmitter, was connected, by mistake, to the lighting circuit. But even then, the lighting circuit should have been capable of withstanding the load of the transmitter without much of a voltage drop. Shortly afterwards I moved the shack downstairs into the garage. At the time I never checked house wiring and later on the family sold the house and moved. The new owner was not a radio amateur.

Reg, G4FGQ.

Hi Reg., The question was certaintly not a few sentences of plain
English. If the enquirer had shortened his description to a few well
defined sentences he might have some answers by now.
The demo version of EZNEC is free, as are your programs. Niether
require 6 weeks to learn.
My advice is to model the antenna, or give more precise question(s).

That would be my guess. Here in the US, at least, it's quite common
for a single 15- or 20-ampere circuit to be used for both wall
outlets, and lighting circuits, in one or more rooms. There's nothing
in the electrical code which requires separation of these sorts of
loads... and in fact I seem to recall a clause which actually forbids
"one outlet per circuit" branches, for some reason.

> But even then, the lighting circuit
>should have been capable of withstanding the load of the transmitter
>without much of a voltage drop.

It doesn't take all that much of a drop in voltage to result in a
visible change in the brightness of an incandescent-filament light.
According to one site I've found, light output is roughly proportional
to the voltage raised to a power between 3.1 and 3.4. A 5% drop in
voltage would thus result in a decrease in light level of more than
15%, which would be pretty easy to notice.

If you were transmitting 100 watts CW key-down, I'd guess that your
transmitter was probably drawing at least 300 watts from the
mains, and perhaps rather more depending on its design.

Add a few more likely or possible elements e.g. a linear power supply
which tends to draw most of its current from the mains during the
voltage peaks (and thus causes a disproportionate amount of voltage
sag on the lines during those peaks), insufficiently-thick house
wiring in the walls, and perhaps a slightly loose or corroded
connection to one of the outlets or switches or breakers, and I can
well believe that keying a 100-watt CW transmitter could cause enough
voltage drop to result in visible dimming of the lamp bulb.

>satisfactory explanation.

To add complexit to this puzzle, was your dinner being cold caused to some extent by the apparent drop in mains voltage at the light socket in the shack (bedroom)?

Did your light have a phase controlled dimmer (you know, to set the mood)... they not only emitted huge quantities of RF, they were also very susceptible to ingress of RF.

It wasn't by chance some other interaction like RF interference with street lighting controllers and the street likes were operating in sympathy with your keying?

Perhaps some other on-site high power appliance affected by RF. I had one of the early heaters with a fully solid state thermostat that was susceptible to RFI, and it took a while to work out why when I went into my office sometimes the heater had been running even though it appeared to be "off"... until I associated the effect with recent on-air activity.

At my coastal retreat, SSB RF was getting into the irrigation controller recently, causing water hammer in sympathy with speech.

There are limitless possibilities!

Got a small tv in Luxembourg, no channels found (trying both SECAM and PAL). I suppose I need an external antenna. Something cheap will likely do the job as signals should be good in this area, but are there any pitfalls to avoid in order to avoid a 100% useless antenna?

Just about anything that conducts electricity will be an improvement
over nothing.

With enough fiddling the old traditional rabbit ears make a pretty good
antenna. Back when antenna lead-ins were a pair of screws you could do
quite well with a couple of coat hangers.

Probably any shop that carries TVs will have something.

Reg;

As I said it was my guess. That's what you get for guessing. It would seem that your house has sufficient capacity to carry a 60 watt light bulb and a 100 watt transmitter.

If you ever find out what happened let the group know.

Maybe I'll meet you on the air some day.

A friend of mine back in the 70's had me come over to listen to his new stereo. It was a Phase Linear system as I recall. The speaker cabinets had 9 components each in them. We put "Hall of the Mountain King" on the turntable and turned up the level to the point just before it began to distort. The power amp was pretty substantial and I noticed the lights were dimming to the music. I went outside and could see the power meter change speed in time to the music. And this was in an industrial building. That was the loudest home stereo system I ever heard. Probably the best sounding as well.

I recommend that you avoid fancy and expensive antennas that sit on top of the TV and have lots of knobs and switches -- those are nearly 100% useless. Begin with what we call "rabbit ears" -- a couple of telescoping rods in a plastic base which you can adjust in length and position. That should be adequate to get some TV signals in an area where the signals are fairly strong. If you have trouble with "ghosts" (multiple images spaced horizontally), you'll need a directional antenna, outside or in the attic.

Hi Jan

My personal favorite indoor TV antenna for use in metropolitan areas is the "Apple Antenna" It is a plastic apple that is attached to the wall and located several feet from the TV set. The Apple Antenna is then connected to one of the two antenna terminals on the rear of the TV with a length of copper wire. The instructions mention that the Apple might need to be relocated for best reception.

==========

Cec, What is ELNEC? OK, I can guess!

Quite truthfully, if you had pointed ME towards EZNEC then I am unable even to download and un-zip it.

Acually, I do have a copy. Some years back Roy took pity on me and, without any request from me, very kindly broke the rules and airmailed me a free parcel of 3.25" floppy disks. It took me a week to print out the instruction handbook and another 2 weeks just to read it by which time I had forgotten what the problem was.

'Experts' should realise, from the manner in which questions are written, the predicament some questioners are in and make allowances instead of leaving them to flounder about in a sea of frustration and despondency.

N4AST's comments are unworthy.

Regards, Reg.

Got a link to a picture of yours? I'd like to see it.

I was running a Master Mobile antenna, about 8 feet long, and the base
at 9 feet off the ground for a while. You have to know your routes pretty
well to do that! <G>

Hmmm, acoustic suspension speakers gobble up a lot of power to get
decent bass. In the 70's a friend was into building stage columns in
his bedroom. He had big 120 dB spl drivers in ceiling high large bins
and it only took a 100 watt (4x6L6's) amp to drive them beyond ground
shaking levels. He would play Tarkus on it, Lucky Man etc. Sound was
great too for vinyl. It is amazing how good vinyl sounded back then.

But 'Experts' need to know the length of the antenna which, to the
best of my knowledge, wasn't given in the original posting. That's
why I recommended EZNEC.

Actually, that's our resident Rec.Radio.CB troll,
Doug Adair N8WWM. Just google N8WWM and see
all the fine writings on record for him. Better yet, go
and google "keyclown" or "keyclownz" in either web
or groups search.

The elements are "linear-loaded" . They are folded back on
themselves.
The phsical length is 70ft.,But the electrical length is 210ft. long
!
Now, is this strange dipole a 140ft. long,OR is it 420ft. long ? ?
That's why the feedline is so much problem.....I've built
over
2 doz. antennas;this one IS tricky ! I have only 1/8 acre of land;
Hence the problems with dipole lengths,and feedline lengths.....:-)

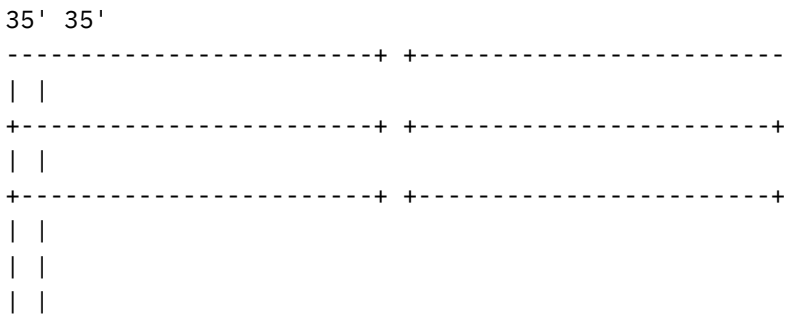
Something like this? (fixed font)



How far apart are the adjacent wires spaced?

Dear Cec,

So, if you had anything to say, why didn't you just ask him how long
is his antenna instead of sending him off on a wild goose chase?

I must admit you got nearer to discovering what was missing than I
did. Let's see what happens now.

Reg, a standing recommendation of mine is to download the free
demo version of EZNEC and have fun learning how to use it.
Any amateur radio operator who succeeds in doing so will be
rewarded for the effort expended (and was also a source of
extreme pleasure in my case). ELNEC/EZNEC and the Smith
Chart (Microsmith) are the most useful tools I have ever
encountered for comprehension of antenna systems. (Not
considering reference books as "tools".)

Dec. is Part II of a three part series titled: "An Energy Analysis
at an Impedance Discontinuity in an RF Transmission Line". Part 1
was in the Oct. issue. Here's an email I got today:

"Oh Boy! What a captivating article re energy analysis at an impedance
discontinuity. Lots of good, fundamental, insight. One of the best
articles that ever appeared in a ham radio publication."

OTOH, somebody else called it "gobbledygook". :-)

His article covers an analysis of energy on a transmission line that
contains impedance discontinuity.

He has covered the subject on this news group and the article is a
compilation of those thoughts.

Enjoyable reading sans the QRM one finds on a newgroup.

Al, VE7AGW wrote:
"I thought Charlie Pride sang that one."

I wouldn`t be surprised. Charlie is a great country singer. When I hear his name, "Kiss a Devil Good Morning" pops into mind. Ray Price mostly owns "For the Good Times." Ray still lives in Texas, rides motorcycles, and has taken up comedy, I suppose, to enlarge his act.

Since Clear Channel Communications, Infinity Broadcasting, etc. bought most of the non-network-owned broadcast outlets, music stations have disappeared. Clear Channel changed the music programming of the last sizeable AM music outlet in Houston to sports programming last year. That was when I found the 680 KHz signal from San Antonio was usually good here 24-hours. I think they run 50-KW nondirectional day time and 10-KW nighttime, pointed away from KNBC in San Francisco at nignt. KNBC is 50-KW, 680 KHz, non-directional day and night.

At night on 680 KHz in Houston, there is somtimes interference from Cuba. The map shows 4 Cuban stations sharing 680 KHz, so there are tales about "El Commandante Fidel" breaking into my night music from San Antonio at times. There are several Mexican stations too, but they seem to try not to interfere. WAPA in San Juan, Puerto Rico is shown as 10 KW non-directional night and day on the map, but I have not noticed interference from them, so I wonder if they are really still there.

For country music in most of North America, a good bet might be "The Grand Ole Opry Station", WSM in Nashville, Tennessee. It is 650 KHz, 50-KW, non-directional, night and day. When I was a kid, this station adveritised itself as "The National Life and Accidennt Station" but already carried "The Opry" The insurance business has shifted about like the broadcasting business. Both are regulated. Insurance by the state and broadcasting by the feds.

My Broadcast Allocation Map Book doesn`t indicate programming. It was only in the earliest days that the Commerce Department ruled that all stations on a certain frequency must only broadcast music. Sometimes the first idea is the best.

Best regards, Richard Harrison, KB5WZI

The good old days as we say, back when the radio stations played non-stop music and the all the girls wore skirts and us guys wore jean and white T-shirt. It's fun but but I remember when the we use to get these radio maps of the world with all the stations listed on them. And as you say they listed the power day/night and most of them only played music no advertising at all. I use to listen to this rock and roll station out of Buffalo called WKBW 960 khz and all they played was rock and roll. American Band Stand with Dave Clark, I suppose this is dating me know. On my last trip back that way I heard the station ID on the FM dial instead of AM and they still played the old rock and roll from the fifty and sixies.
Talking about cournty and western station in Texas, well I use run truck loads of red cedar to this place in Grande Pairie Texas, right between Fort Worth and Dallis and I would listen to this am station from Amarillo. Could pick it up just outside of Dallas while running up US 287/87 to Denver then shortly outside of Denver I would loose it. The loneliest section of road for radio station is Montana you just don't pick up much at all even on Am. And Fm is usless in most places except around big cities.
The last Freightliner I had I put the satelite radio in it and had radio everywhere then and lots to choose from too. Even had my Icom IC-706 in it as well.

Cec, as an aside, when people are conversing with each other, 50 percent of the information passing to and fro is conveyed by body language.

Body language is completely lacking when conversing via newsgroups. This can very easily lead to misunderstanding and futile argument.

People should check and recheck what they have said before posting. The existence of certain types of spelling mistakes and obvious grammatical errors are a guide to the care and attention which has been paid by the sender to saying what he intended to say.

I admit, very careless senders do not deserve any replies. Not because absence of reply is an unsaid reprimand but because they have indicated their inability to understand a reply if they get one.

Then there are trollers!

This message is primarily intended for people seeking solutions to problems.

I have had only two glasses of white wine. (South African).

And I don't know how to use a spell-checker even if I had one.

Yours, Reg, G4FGQ

Dear Cec,

In the present context, in the absence of body language, your praise of EZNEC can perhaps be misconstrued as my criticism of that erstwhile computer program.

On the contrary, I quite agree with your comments.

Regarding the Smith Chart, I have myself never found it to be of any use. In fact I don't know how to use it. I am aware of its long-standing existence, and what it is purported to achieve, from this newsgroup and from the one or two ancient 'bibles' which I seldom refer to.

But the absence of a Smith Chart may be due to some vague shortcoming in my education for which I have no responsibility. So I have never felt myself to be handicapped in any way. Indeed, I have gained from this and other websites the impression that I am considered to be a transmission line 'expert'. But I claim only to be a well-educated, useful engineer who also happens, in retirement, to be a radio amateur with the ability to express myself in plain written English.

To continue with my earlier message, I have just finished a third glass of white, South African wine.

But enough about me. What are you doing about Bush?

Reg.

If you live within about 30 km from a station, you should be able to get some kind of a picture with nothing more than a 1 meter piece of wire connected to the antenna terminal. Make sure the TV is set for antenna, not cable. Don't k now the European frequency plan, but here in the US, TV channels 14 and above are offset by 1/3 of a channel from cable channels in the same frequency range.

I believe that REG and CECIL have lost the idea of what I asked in
the begining.
I'm NOT a dog going around in a circle chasing his tail ! I want
some FACTS.
NOT endless chatter, about the worlds demise!
I have a bought antenna made of wire. Yes, I should
have built it
myself,BUT I didn't. I need to know how to fix "said" antenna, and
intergrate
it into my small land. 1/8 of an acre. ON4UN's book on "low band
dxing"
states that there aren't any PROGRAMS for linear-loaded ant.'s out
there.
oh well, I guess that
I'll just haffta go back to 2m !

That may be true but if we space the parallel conductors
a foot apart, take a look with EZNEC, and it's a dog of
an antenna, we can draw certain conclusions about the
closer spacing of your antenna.

"I just haven`t found the right person who will help."

Help, it seems, is the answer Paladin wants to hear. When you want to put 8 pounds of crap in a 4-pound bag, life is often that way. You quickly run out of good advice.

When a respondent says there`s no computer program to tell you how to linearly-load an antenna wire, you are invited to prove him wrong. The ARRL Antenna Book says:
"Since the dimensions and spacing of linear-loading devices vary greatly from one antenna to another, the best way to employ this technique is to try a length of conductor 10% to 20% longer than the difference between the shortened antenna and the full-size dimension for the linear-loading device. Then use te "cut-anhd-try" method, varying both the spacing and length of the loading device to optimize the match."

You might write a program for that.

Best regards, Richard Harrison, KB5WZI

Hi OM,

It's "supposed to work" is the key phrase here - according to who?
Perhaps this is your greatest difficulty in finding help for a design
that won't be helped.

> It wouldn't cover the lower portions of 160. To get this antenna to
>work on 160, I had to cut
> off 20ft. of ladderline, AND also use a 50ft. piece of coax! I tried
>using only 20ft. of coax
> because that's all I need to get to my tuner,but it didn't work! ! !

Your statement here contains a great degree of success in it. It
would appear that you have higher expectations than could be
reasonably expected.

>Why are the signals that I rercieve on the higher
>bands,(160-10m) usually SO LOW in strength ? Ex: On 160 or 80,the antennas s-meter
>usually reads over s-9 at night,o.k. Now, the same antenna on 10m or 20m during
>the day are reading very low; mostly around 3's and 4's.

The linear loading that you have described in further correspondence
is not particularly remarkable. It follows the aphorism to put more
wire higher into the air, but in reality, that more wire also needs
more volume (surface area, what-have-you). The triple-backed rotor
cable has been trotted out here before, and has never been shown to be
anything but a good match - perhaps. You can load a resistor to the
same effect and you may note similar performance issues in that
correlation.

If you want to keep more wire in the air, build a fantail dipole or a
cage dipole and use more than three wires (six to a dozen instead)
with a truly large, effective diameter at the end.

Hi Cecil, that's what I understand. To a first approximation, on 160 meters, the radiation from the two segments furthest from the feed point should cancel. That would leave the effective antenna as a shortened dipole with a length of 55 degrees per leg [two 80 foot long segments per side]. This should yield a radiation resistance of somewhere around 10 to 15 ohms with a significant capacitive reactance of between 500 to 1000 ohms.

His 100 foot long feed line is only 69 degrees long. I believe this short a matching section, i.e. "stub", may be insufficient to achieve a '50 ohm' match.

I would expect the antenna gain to be -2 to -3 dBd.

Comments??

Probably because it covered DIGITAL TV. They have a few analog channels. The last time I was there they had BBC1 and BBC2 on VHF. What I found interesting is that a lot of Europe uses vertical polarization rather than horizontal like we do. Every time I go over there it takes me a few days to get use to the 50 Cycle refresh rate which I perceive as flicker. But at least the "colour" is the same from all cameras.

Total cost about $10. Takes about an hour total time. No permanent modifications to original antenna. Web page includes complete fabrication and assembly instructions. Also included is final test data showing swr at <1.3:1 across all 7 bands of a modified Hustler 5-BTV. Some retuning of 20M is usually needed after 12M and 17M are installed and tuned. Mod consists of a 12M 1/4 wave radiator and a similar 17M 1/4 wave radiator installed along side antenna held with 4 Plexiglas spreaders which are home brewed. Takes legal limit.....looks good...works good too!

Tired of "contesters" jamming up the bands nearly every weekend? Find refuge on 12M and 17M !!!

If you are trying to use this in the North American, South American
markets, no wonder it doesnt work! North american uses NTSC standard,
while PAL/and SECAM are European standards! Think there is also another
standard for Austrailia/New Zeland, tho they might also use PAL.
(and this is before you consider the tv station frequencies difference)!

Fred, W4JLE wropte:
"Can`t believe you left out WCKY Cincinnati 1 Ohio."

WCKY 1530 KHz should not be omitted from any list of great radio stations accessible to millions of listeners. I made no list. I picked only one station I thought might best typify country music and be widely propagated.

WCKY is 50 KW nondirectional daytime but uses a n-s directional pattern which places a sharp null toward KFBK Sacremento, California. KFBK also uses 50 KW but in a north-south directional pattern up and down the west coast of the U.S.A.. This tends to protect WCKY, too.

WSM always has a 50 KW nondirectional pattern. That is now the maximum power allowed AM broadcasting in the U.S.A. When I was a kid, another Cincinnati station, WLW was called the "Nation`s Station" and broadcast with 500,000 watts. It really could be heard almost everywhere.

WSM is exceptional due to programming. It originates the "Grand Ole Opry". A network of more than 100 stations carry the program in several countries. It also feeds the Armed Forces Radiom Service.

WSM at 650 KHz is toward the low-frequency end of the AM broadcast band and that tends to propagate day or night better than the high end of the band.

Dolly Parton is a regular on the Opry and that trumps all other reasons for picking WSM as a favorite.

Best regards, Richard harrison, KB5WZI

> ground conductivities around their various azimuth sectors and ranges.
>
> Have fun.

Just a FYI...the contour maps at Radio-Locator.com are WRONG....the LOCAL on
FM maps is actually the distant or Service Contour (1mv or 60dbu
level)..LOCAL is defined as City Grade or 70dbu or 3.16mV level...which they
do not show..On AM, they show lower levels on the map as well...If you want
to really know what the signal level should be, draw another circle or line
inside the LOCAL one they show...about the same distance between the LOCAL
and Distant they show...Your line drawn will be local, their local becomes
Distant and their Distant becomes Finge...
Their Fringe is now DX :)

Fred, If you notice the document
(http://www.digitaltelevision.gov.uk/pdf_documents/publications/DTT_Reception_Impact_Analysis_Ver_1.0.pdf)
does refer to analog transmission in the UHF band.

According to http://en.wikipedia.org/wiki/VHF:
"British television originally used VHF bands I and III. Television on VHF was in black and white with 405-line display. British colour television was broadcast on UHF (channels 21-69), beginning in the late 1960s. TV from then on was broadcast on both VHF and UHF, with the exception of BBC2 (which had always broadcast solely on UHF). The last British VHF TV transmitters closed down on January 3, 1985. VHF band III is now used in the UK for digital audio broadcasting. Unusually, the UK has an amateur radio allocation at 4 metres, 70-70.5 MHz."

Possibly somebody from the UK could verify if all the VHF stations have in fact closed down. It is true that they use vertical polarization. The refresh rate is 25 Hz, interlaced, which is why the flicker is so noticeable. NTSC color drift was cured in the late 70s. PAL was a genuine attempt to fix the color drift problem -- with some loss of color resolution. SECAM was invented by the French to be different to everybody else.

Regards,

Frank

I wonder if you are right. Looked at the original posting, and noticed he
did not exactly say he *lived* in Luxenburg. BTW, some of these countries
use 60 Hz PAL, which would not work with a set bought in EU either. RF
frequencies are guaranteed not to line up, because the channel spacing is
different.

Yes, nice photos. 17 meters is a great band, not just for refuge from
contesters.

Your 1/4 wave addition reminds me of the Cushcraft design for the R8
antenna.
The R8 uses 4 stubs for 15, 12, 10 and 6 meters, which leaves only 2 traps
for 17/20 and 30 meters. A builder could probably even order the 2 hole
insulator (Part # 205097 - R8 antenna) for this project.

I want to build a 1.2 Ghz antenna for this tiny wireless camera receiver I have. The antenna on it uses an F connector so I am guessing it is a 75 ohm antenna. I have seen several web pages with a collinear design using 50 ohm coax cable. If I use some 75 ohm cable TV coax to make the antenna do I need to do anything else to match the antenna to the 75 ohms of the RX? Also does anyone know what eh velocity factor for the coax the cable company uses is?

Chris,

If you are talking about "one off" installation, don't worry about the 75 or 50 Ohms coax. As you say, 75 Ohms seems to be the correct guess as it's a F connector and as the TV world seems to be in love with the 75 Ohms cables/connectors.

You don't really need to be bothered by matching your 50 to 75 Ohms. Most cables and connectors deviate so much as +/- 50% on the actual impedance anyway. The loss tends to be lower in 75 Ohms cables.

If you are concerned over the match, make a Y coax match (Wilkinson ?) You find the recipe for a stup or an Y match in most amateur radio cook books.

The easiest way to make a small aerial for 1.2 GHz (Weird frequency for a wireless camera?!) is to make up a small Yagi aerial on a double sided PCB. You can also make a nice log periodic on a double sided PCB that works for both 1.2 and 2.4GHz. --- Unless you want an omnidirectional aerial of course!

Cheers

Dan / M0DFI

Their maps DO correctly show the distances to the contours for the field strengths they identify. Radio-Locator picked different field strength values for the "local" etc contours than those used by the FCC, but that doesn't invalidate the Radio-Locator maps.

And their choices are reasonable. For example on AM, a 2.5 mV/m signal (Radio-Locator's local contour) does provide good service to a typical cheap table radio inside a home in an urban setting.

Hi Chris

Are you considering building a highly directive collinear antenna like
Brian Oblivion + Capt Kaboom describe on their web site? If so, be sure
to use a coax that you can solder to. Some RG-6 wont take solder. The
RG-6 dielectric is foamed poly, so that makes it a little more difficult to
solder than to Teflon dielectric cables.
The velocity of propagation of RG-6 is not constant. It depends on the
manufacturer. The VP is close to 0.8, but can vary from about 0.75 to
0.85.

If you plan high directivity from an end fed collinear, you will need to
be very careful to build it with precision to produce a main beam thats
perpendicular to it.

The nice part of the "Kaboom" type collinear antenna is it is very
inexpensive to build so you can build one and try it, then make another
thats a bit closer to your requirements (if needed).

So anyhow, is there some interesting discussion to be had on this antenna? Richard Clark started to touch on it, but I'd like to hear more.

As a true dilletante (so take my advice with a grain of salt), I would have to expect that the antenna isn't going to work all that well, and the wellness of working is going to decrease as the frequency goes down.

Putting more wire in the air generally works, but putting all that wire right next to another wire that is part of the same antenna could make for some issues.

In "short" I suspect that your antenna will work out on the higher bands, but even if you get a match on 160, it won't be too awesome there.

Some other factors with your tuning are going to be height above the ground. I always seem to misoverestimate my height above ground. Was there a suggested height for this antenna?

Hopefully this helps. just remember, I'm no antenna Guru.

The rubber gaskets around the rear door of SUVs are very accommodating to small coax. Since you are doing a short run, sounds like VHF/UHF, this would accommodate your vertical with an antenna clamp attached to the rear door. Could use RG-58 or RG-59 since it is a short run to your radio.

Good Luck,

Bill, W4WNT

Hi OM,

Well, you still have options.

Tie all the wires together and use them as a top hat to a vertical.
Verticals have far more reported success on 160M than horizontals.

Of course, you will need to plant more copper in the ground than you
lifted into the air....

Strangely, most Moore's claim not to be related to me. ;-)

> John Moore, however, does claim to have attended Texas A&M with Cecil.

Yep, I've got the yearbook to prove it. John's a good guy.

> When names were chosen, it seems more would likely choose the name Moore
> than the name Less. Why are there not more "Mosts"?

Actually, when the English government decreed that everyone had
to adopt a last name, a host of people who lived out on The Moors
adopted that last name. Some of them may not have been related
even back then, except by geography.

Richard, your last name might have been adopted by someone whose
father was named Harry. Smith probably came from Blacksmith,
Potter from a pottery maker, Johnson from John's son, etc.

The Discovery Channel's "Longitude" featured the considerable
talents of John Harrison, a cabinet maker more famous for his
timepieces than for his cabinets. (Wonder why they didn't just
use the GPS system? :-)

I`d like to claim kinship with John Harrison who built the first chronometer accurate enough to compute longitude, but I can`t. Parliament had offered a huge cash award for such a timepiece or other means of accurately determning longitude. John proved he had won, then tried for years to get full paynent from parliament. Finally John got an audience with the King who declared: "By God, you shall get your payment!", and he was paid. Now, John Harrison is a big feature at the National Maritime Museum at Greenwich. Some of the wooden clocks, gears and all, that John built are still in use and keeping time well. The chronometer is more like a large pocket watch.

GPS is huge. You can immediately know within a few feet exactly where you are, unless you happened to be the target.

There are boat trips on the Thames between London and Greenwich. If the weather is good, it is very pleasant.

I saw that program on public TV some time back, and highly recommend it
-- it was very interesting.

Some years ago I saw a display on timekeeping at the Smithsonian which
explained and gave an example of each of the advances and innovations in
clockmaking which improved timekeeping accuracy. The last item at the
end of the display was a few-dollar Timex digital watch which, the
caption said, was more accurate than any of the mechanical predecessors.

Wolfman Jack (Bob Smith) is immortalized in the movie "American Graffiti", where he plays himself. He died in 1995 at age 56. There's a lot about him on the web. See, for example http://en.wikipedia.org/wiki/Wolfman_Jack.

I know what you mean, Paladin! And 160 meters is a real booger of a band for most of us to have a horizontal antenna. There are loaded antennas, but I suspect you want multiband performance. I suspect you could tune a loaded antenna cut for 160 meters, but I'd also expect that the radiation pattern on the highest bands would be a bit weird.

Speaking of weird, I wonder in anyone has made a multiband antenna, loaded on 160, and trapped for the other bands? 8^)

What might be a good setup to get you on 160 meters and more would be a vertical antenna. They are a compromise, but most top band antennas are. AFAIC, they are a compromise on most of the other bands too. That is why I have a dipole in addition to a Butternut HF6V.

******* Copied from uk.radio.amateur newsgroup. ********

> Reg spoke of the SWR meter as a resistance bridge. It is possible to
build a
> meter that is a bridge
==========

The so-called SWR meter is ALWAYS a resistance bridge (although it may
be described in other terms).

In the HF, 100 watt models, the little ferrite ring is a current
transformer. The turns ratio on the transformer allows the bridge
resistors to be changed to values other than 50-ohms.

For example a bridge resistor which is across the transmitter changes
to 5000 ohms. And a bridge resistor in series with the load changes
to 0.5 ohms. In both cases the power lost in the resistors falls to
the order of 1% of the power which would be lost in 50 ohm resistors.

The meter becomes far more power efficient. With 50-ohm bridge ratio
arms the power lost in the bridge would be 75 percent of Tx power
output.

The 0.5-ohm resistor does not exist. Very cleverly, the input
resistance of the one turn primary winding on the current transformer
becomes the 0.5-ohm bridge arm.

The DC seperation between primary and secondary windings on the
current transformer allows the diode rectifier and moving coil DC
microameter circuit to be operated very nicely all at ground
potential.

Reg, G4FGQ

The term 'meter' is incorrect. It does not 'measure' anything. It
merely 'indicates'.

> Tam/WB2TT

The rotator has an odd connector - 6 pin from memory - but I should be
able to do something about that. I really want to see the rotator's
circuit before deciding if I feel like making a control unit. It
shouldn't be too difficult if it comprises just a motor, potentiometer
and limit switches. The most important bits to me are the mechanical parts -
I can't make them.
Thanks to the other poster who replied - I found most of the references
on the 'net to be a bit lacking in the detail I need.
Alan

Hi Roy,

The better majority of listings cite XERF, certainly, but seem as
likely to obliquely refer to XELO whose call letters seemed to be
re-assigned on a whim. One thing I have no doubt of, tho', is that
guttural rasp announcing "from Del Reee o Texas."

Hi,

I am looking for a new Car Radio/CD, to solve terrible reception problems I have
- probably a manufacturing flaw with the car the manufacurer supplied radio- changed both (to same model) and the problems presist, no FM station holds for more than a minute anyhwere in the country- either in manual and auto scan, while in my house even the cheapest radio transistor works fine.

I thought of DEHP4750MP Pioneer, it lists "IIID SuperTuner" as a feature, whatever that is?
Then saw that it doesn't support RDS. Seems strange for such an advanced piece of technology. Anyway in another Cadence model, it is advertised as having "Radio sensitivity" of 10dB-UV to 30dB, what does that mean and what values should I be looking for to get maximum sensitivity?

thank you!

> otherwise.
>
Totally off topic, but you do know what "liberal" really means when used to describe political ideals, right? I mean, you've looked it up as it is used in political studies or anthropology? This word gets a lot of use in today's polemics (especially in the US, where it has become quite the loaded term) but it is usually misapplied in this context. To the point of being used in the exact opposite from the definition. That is, not just simple connotative slip.

(For some reason, the line from _The Princess Bride_ came to mind, "You keep using that word. I do not think it means what you think it means.")

(Inconceivable!)

Also, I'm pretty sure you don't know your president personally, so it is technically a fallacy to say "he is a good man." Perhaps you surmise from his actions (or the second-hand, imperfect, reports of such actions) that he has qualities you admire? The problem, of course, is that just as many people could come to the opposite determination of the president being a "bad man" by the very same actions. I mean, how does one know if they are the one being brain-washed or not?

I'm also puzzled why one would espouse total support of a "Commander-in-Chief" simply because he is "the Chief." I'm not singling you out, as I see examples of this sentiment everywhere (i.e., not just in the US.) It seems to go against the principles of democracy and informed citizenry. I don't think I'm exaggerating when I say that such a sentiment is more a fundamental marker of totalitarianism.

3685. TDA1083 IC, I need help.

Hi all,

Happy Thanksgiving!

I am looking at the TDA1083 IC. The datasheet shows the following
image:
http://img120.imageshack.us/img120/2720/tda1083blockdiagram1sr.jpg

I'm trying to figure out where the input for the FM signal goes. This
IC is supposed to be an AM/FM receiver, but this newbie is a bit
clueless as to where the FM antenna and matching network should be
connected.

Any tips?

I figured there are many veterans here who have messed around with
radio ICs, so I'm trying my luck here.

Thanks!

Hi MRW, the Homebrew Group might be a better place to ask this. Looking at the IC, it appears you need an external Local Oscillator and Mixer for the FM section, and that is where the rf input for the FM section should go. Looks like it has an LO and mixer for AM on the IC. I have never used this IC.

Is saying bad things about people you don't know morally equivalent to
saying good things about them? Some people believe that if it is
repeated often enough and long enough, it will become so.

> I'm also puzzled why one would espouse total support of a
> "Commander-in-Chief" simply because he is "the Chief."

The not-so clvr mnky might consider that to those for whom the current
Commander-in-Chief is Commander-in-Chief, it's pretty clear whose side
he is on.

First, why on earth do you want to use this old chip?! There are plenty
around that are easier to interface as well as almost complete receivers.

Could you please tell us what you actually want to do so we can point you in
the correct direction.

Cheers

Dan

If you can find a data sheet there should be a sample circuit, or a test
circuit. These can be invaluable for showing what the designers were
thinking.

Bingo!

Little Acun~a has now grown to Ciudade Acun~a, Studios were in Del Rio, Texas, I believe.

There is a book I found interesting about super-power broadcasting from the banks of the Rio Grande. I think the title was "Border Radio". It began with Dr. Brinkley, a chiropractor I believe, who advertised monkey and goat gland implants for remediation of erectile dysfunction. It ended with the RCA Ampliphase monster that RCA installed, and abanoned across the Rio when they could not meet specs. Consultants hired by the buyer made it work as advertised after a long struggle with RCA. Between these stories were tales of some of the other colorful characters who broadcast on these high powered stations.

Best regards, Richard Harrison, KB5WZI

Hi MrW

Try Googling "one chip am/fm dadio with power amlifier tda1083". ATMEL Wireless show a complete circuit diagram, including the antenna connection. That looks like an interesting/worthwhile project. Good luck.

Your question puzzles me. I don't recall making any value statements,
or mentioning any moral imperatives. People say things. Other people
hear them, or hear about it from others. We can only arrive at some
concrete value for abstracts like "good" or "true" by consensus and
examination.

We have met the enemy, and he is us!

Seriously, I have no idea what you are driving at. Whose side is who
on? I was speaking to the notion that tautologies such as "I support
the chief because he is the chief" seem odd to me. Even the inverse is
a tautology.

Slightly OT, but kinda fun anyhow.....

I'd been trying to locate a reasonably priced USB cable over the weekend It seems that you often pay as much for the cable as you fo for the device you are connecting to the computer.

Has stereo voodoo physics entered the computer realm?

Anyhow, I ended up in a Radio Shack store, found the cheapest cable I could, (20 bucks) and made the mistake of mentioning something to the salesman about the funny claims on the packages. Big mistake, I had blasphemed his religion. In the next couple minutes I learned that:

Turns out that different frequencies travel at different speeds down the cable. Good cables have special formulations of wire that compensate for this.

Everybody knows that!

He didn't know what velocity factor was, but let me know that he had taken physics classes, so he knew what he was talking about.

So why have u antenna gurus been misleading us?!

Now that my eyes have been opened I understand....

Looking at an antenna, it becomes obvious that the lower the frequency, the slower the signal moves. The extra length of the antenna allows the RF to accellerate enough so that when it reached the end of the antenna, it has enough velocity to shoot out and not float straight up. Those really high frequencies are zipping by so fast that they hardly need any wire to get to TOSP (Take-off speed)

Wow, I have reached true enlightenment.............

you didn't know that? its called frequency dispersion. fortunately it is a
relatively small effect and in normal bandwidths hams use it can be ignored.
for very high bandwidth signals like high speed digital stuff it can badly
distort the waveforms and can be the limiting factor in determining maximum
cable lengths without repeaters.

Too much ruckus has been focused on the 'No Code License' issue.
The ruckus should, instead, be focused on the 'No Clue License'.

Oh yes, I've heard of dispersion. But that isn't what the guy was
talking about in our context. He was talking about gross effects.

I never mentioned the no-code licence... we got over that over a year
ago down under.

I suggest it is not a matter of the no-clue licence, but the no-clue
licensee, who could be licensed in any grade.

i was trying to figure loosly in real world case

what the difference would be (generally speaking) between say a verticle all band commercial antenna on my roof (of my tall apt building) i'd naturally install it's radial kit

vs

a equal all band (yeah i know it'd be tall) virticle dipole (tweeked w/a tuner sgc at feedpoint

would i suspect they would perform about the same or dramatically different?

all band defined as 80-10m

thanks all and happy thanks giving

3707. Re: Plans for B&W BWD-65 & BWD-90 Folded Dipole Balun & Terminating Resistor

Newsgroup: rec.radio.amateur.antenna

Hi Dave,
The resistor is manufactured right here under indent in Brazil,
the balun I build for myself using 8 ferrite beads in material 43 OD =
15mm ID = 8mm...
with each 4 of them I make a tube gluing them and soon after I glue the
two tubes forming a binocular core. In it I wind two turns of 16AWG wire
and a bifilar wound of 4 turns done with the same wire on the first 2
turns...Of this wound, I joint the begins of a wire in order to the end
of the other wire, placing them in against-phase...The extremities that
remain will be the high impedance (about 800 Ohms) out to the antenna,
them points that were united will join to one of the points of the
first wound, which will go to the GND and the point that it remains of
the first wound will be the inner of the 50 Ohms coax connector
(SO239)... But, it is for low power power... For 1500 Watts you should
find the core and the appropriate wire...
I hope it can help you...
Best 73's,
Silva.

You can increase the velocity factor (and shorten the antenna) by using
a good grade of Carnuba automobile wax to make the antenna slipperyer,
which (because of skin effect) allows the signal to accelerate faster.

> one know if they are the one being brain-washed or not?

Fundamental differences in what people believe (e.g., preemptive action versus complacency) will determine their opinion.

>Is saying bad things about people you don't know morally equivalent to
>saying good things about them?

I'm not convinced that saying bad things about someone you don't know has any moral value at all, unless one's negative image of that person is based upon that person's actions and beliefs.

> I'm also puzzled why one would espouse total support of a
> "Commander-in-Chief" simply because he is "the Chief."

You're puzzled due to the fact that you've never served in the armed forces of the United States.

Yah but it makes receiving signals harder because the incoming radio
waves find it hard to stick to the antenna. They slip off in the wind.

Funny that you brought this up today, Mike. I happened to hit my local
RadShack yesterday in search of a Cinch-Jones power connector. I told
the salesman what I was looking for, an 8-pin Jones plug/socket set. He
asked if I was looking for a microphone connector. I explained what the
Jones plugs looked like and told him that they used to be standard fare
in at Radio Shack and that they stocked them in 2, 4 and 8 pin
varieties. He told me that he'd never seen nor heard of them.

I told him that I could likely use a strip of the European-style nylon electrical connectors with screw terminals. He'd never heard of those and said RadShack didn't stock them. I walked to a different section of the store and pulled two of them off the rack.

I've gotten into several heated discussions with audio weenies over oxygen-free cable, gold-plated connectors, carbon vs. metal film resistors and mylar vs. paper capacitors. All of these guys swore up and down that they could hear a difference in one item vs. the other. I've offered to set up blind tests to see if they could, but none would ever take me up on the offer.

BTW, Mike, Big Lots, Value City and WalMart usually have a variety of
USB cables from $4.99 to $7.99.

3720. Antenna reception theory

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-24 18:25:21 UTC
From: Paul Taylor <pault_rem_.ngea@virgin.net>
Message-ID: <pan.2005.11.24.18.25.20.956624@virgin.net>
Source record: 67517

Hi,

I am looking for an explanation of how an antenna receives a signal due to the E-field of an electromagnetic wave.

I have looked in some books, and can understand transmission, but the books I have looked in don't explain reception.

I have found an explanation of how the H-field induces a signal in a loop antenna: a changing magnetic flux will induce a current.

But what about the E-field and a dipole antenna? I guess that the E-field causes electrons to move in the antenna wire, because in a solid conductor, electrons will move until the E-field inside the solid is cancelled out?

I have googled but having difficulty finding a good explanation. Any pointers?

Thanks & regards,

Paul.

==========

It is impossible for an E-field to exist without an H-field.

Therefore, antennas of all sorts receive signals in the same way as a
simple loop. Calculations can begin using either the E-field or the
H-field but they both give the same answer.

It's quite legal for traders to charge whatever price they think the
buyer can afford.

On the other hand, it is also quite legal for the buyer to haggle
about it. It's entirely up to you if you are unhappy.

Transmission and reception work essentially the same way -- if an
antenna induces a certain field pattern in space, then that same field
pattern will induce the same voltages going the other way.

Most books spend about that much space telling you about the principal,
then use the rest of the time telling you how antennas transmit, leaving
it to you to figure out how they receive.

This is another example of quantum physics being easier
to understand than Maxwell's equations. RF photons are
absorbed by free electrons in the copper antenna causing
RF currents to flow in the antenna wire.

In the third edition of the _Antenna Engineering Handbook_ there is an article on surface-wave antennas which includes dielectric antennas starting on page 12-8.

Correct. I have personally met more extras without a clue than
generals, and that's not percentage-wise. Your personal mileage may
vary, but a lot of extras seem to be really code oriented or contest
oriented, and did nothing but memorize the technical questions answers
(US) to pass.

I do not maean to disparage anyone who got their license by legitimate
means.

Wasn't there a scandal around that sort of thing a while ago. The name
West comes to mind, but I truthfully don't remember anything more than that.

My old roommate and I used to build biamped, pink noise equalized systems for the bars in the northern NY area in the late 70's early 80's. All Altec speakers with homemade Altec cabinet designs per their white papers.

There was a speaker comparison being done at a local place by a company I don't remember which was promoting a new whizbang super speaker. It had some new tweeter assembly. They had a blind test with 3 speakers behind an audio transparent curtain. They said their's was there, a Kenwood set was there, and an Altec set was there.

We said (order presented) #1 was Kenwood, #2 Altec, #3 crap. #2 by far the best. They said we nailed it brand wise, and were not happy with us otherwise.

Happened more than once, too. A lot of nonsense was happening then, like flame tweeters and other junk.

And from what I've seen, nothing has changed, Bose is still selling millions of dollars of crap.

Of course. And entirely up to me if I go into the store again.

> On the other hand, it is also quite legal for the buyer to haggle
> about it. It's entirely up to you if you are unhappy.

I'm trying to guage the reaction from the RS folks if I haggled over
the price!

My main point wasn't the price anyhoo, but the snake oil science used
to sell the "superior" cables. RS has no monopoly on that.

I've had trouble in the past with cables. Once with a too long SCSI
cable. But that was just a velocity vs timing, and a cheap-o video cable
that didn't have good shielding.

But those things make sense, not exotic wire formulations that speed up
or slow down certain frequencies.....

Sigh.... and then a few months later RS pulls the parts because "no one
is buying this stuff", and puts up more cell phone posters....

All because some doofus doesn't know inventory. 8^(

I don't want to diss my local shack too much tho'. They are the nearest
one to the local University, and they keep a pretty fair stock. Probably
because the Electro-geek level is a little higher than some other
places.I shop there when possible to help keep it going.

It's just like testing ESP, or spoon bending. Something in the testing
process just changes something. You might ask those weenies if they have
any of those rocks that you are supposed to place someplace or another
to make the sound better.

They actually have a few of 'em, Cecil. Our area stores keep them in
metal drawers now rather than hanging them on the wall.

For antenna to receive it must also transmit part of the signal it
intercepts. Now that confuses this discussion a little more, doesn't
it?!

Oh, they had them hanging on the wall but said they didn't
have any. When I found them, they asked, "How do you know
that's a Molex connector?" :-)

Adopted from the IC-22S 30 years ago, I still use the 4-pin
version for low current 12 volt power in my shack and in my
pickup.

Source record: 67442

Most authors explain how a wave is generated, then resort to reciprocity to explain the reception process. But a clear and simple direct explanation appears in Bailey, _TV and Other Receiving Antennas_ (pp. 141-2), of what happens when an electromagnetic wave strikes a conductor:

"The second, and equally important effect [the first being reflection of much of the incident energy] is that some energy /does/ enter the outer skin of the conductor. That part of the energy, which is not reflected, must enter the conductor. The conditions at the surface of the conductor, as we have already seen, give rise to a small resultant electric vector and a large resultant magnetic vector. The presence of these at the conductor is direct evidence that power is entering the conductor. The small electric vector acts on the internal electrons of the conductor and impresses a direction force, tending to drive the electrons along the skin of the conductor in the direction of the electric vector. But from experience we know that /no/ electrons can ever be caused to move without gradually establishing their own magnetic field, and this usually takes /time/. The motion of electrons (which is electric current by definition) never takes place without the magnetic field. How, then, is the electric vector from the electromagnetic wave going to put these electrons in motion? It can only do so because the electromagnetic wave /also supplies a magnetic vector/ as well as an electric vector. And the value of this magnetic vector is exactly proportioned to supply just the right amount of magnetic field energy which the electrons require for immediate motion. Thus the electrons do not have to establish their own magnetic field, since this field is supplied by the electromagnetic wave. Hence, electromagnetic wave energy entering the conductor establishes immediate motion of electrons /along/ the conductor, the direction of motion at any instant corresponding to the direction of the electric vector. If the electric vector changes direction, the electrons will follow suit."

Other posters have correctly pointed out that an antenna doesn't and can't receive a signal solely due to the E field; a time-changing E field can't exist without an accompanying time-changing H field.

I couldn't wait to be old enough to go to tech so I tried the light
socket test at home at age 7. Thus begun my lifetime love of communications
and electronics! The results of the experiments proved so valid that I never
again had the need to revalidate!

My son took and electronics course at Benson High School in Portland Oregon. The teacher was totally clueless and just made things up as he went along. One of them was that the higher the voltage on a wire, the faster it travels in the wire. It took me all day to make my son believe that his teacher was just a clueless sot and to understand ohms law. From my son's perspective, a teacher must really know something to be a teacher. Sadly, this is far from true.

The good news was that I was forced to take a more active part in his education about electronics. We built and tested projects together and it was good for both of us.

It's interesting you mention that, Tom.

I just got my Extra last month. Now, I admit I am not an electronics expert. I had to study really hard before I felt I could take the test. What was funny was actually taking the test.

There were a total of six people testing. Myself and five others. Two going for Technician, two going for General, and two going for Extra (myself and one other guy I didn't know). So, I'm pounding away on the calculator and the other Extra finishes before anyone. He must have only taken ten minutes, if that. He had to of memorized the answers. Actually there were a total of three people who had to have memorized the questions. No way they could have finished so fast. Actually, I was the only one who brought a calculator, so that tells you something.

What was really interesting to me was that the other Extra had now passed all the writtens, but had never passed the 5 WPM code test. So, no HF priveleges until he does that.

I was licensed fifteen years ago and got up through Advanced and took the code tests. But I moved out of state and never got around to taking the Extra. Now, it's all changed and there are only three tests.

Anyway, interesting experience.

I built my first light bulb at the age of 8 -- I used a test tube
from a chemistry set of mine and about 10" of bare copper wire that
I found in my dad's ham shack (the original W3DHJ). Hell, it sure
looked a lot like a light bulb! Then I poked it into the wall outlet
in my bedroom. BIG TIME mistake! I was an Army Brat and we were living
in conscripted housing in Bremerhaven, Germany at the time....
Thus began my lifetime love of of all things electronical.

(-: I suppose this OT thread should be in rec.radio.amateur.homebrew. :-)

Instead of studying electronics you should have been studying the qusetion
and answer book. When the questions are the same as in the book , it is no
use learning anything for a test.
I had the tech license for about 25 years. Just did not want to take time
for the code and did not care anything for the lowbands anyway. The job I
had gave me some free time on the night shift so I finally decided to take
in some code tapes and learn the code on company time. Went to Advanced and
about a year later the Extra. I never did get a chance to look at the Q&A
book. I did not need a calculator fo rthe tests. The answers are usualy
broad enough you can almost guess at them and a quick check with a pencil
and paper will do.

I have not seen the new Extra exam but the old one was very easy compaired to the old Advanced exam. By the way, in 1972 when I took the First Class Phone license there were no calculators or Q&A books with the exect Q&As.

Hi,

Thanks for the replies. I also found a sentence in Joseph Carr's
book, Practical Antenna Handbook second edition. On page 297: 'Large
loop antennas are sensitive primarily to the electric field
of the electromagnetic radio wave, but small loop antenna are primarily
sensitive to the magnetic field of an EM wave.'

I understand that the receiver antenna works in a reciprocal way to
transmit, but if there are other descriptions out there concentrating on
how antennas work at the receiving end, I would be interested to know.

Regards,

Paul.

But it does happen. Back in the 20 WPM days, maybe ten years ago, one ham I know .. who was a former Navy telegraph op .. passed the written part by memorizing every Q&A. And it showed: He was a technical know-nothing. Nice guy, though.

Cecil, I'm glad you passed your Extra exam without difficulty.

But I have to point out that there are many exam questions not
covered in EE (e.g., band breaks and OSCAR schemes); and
NONE of the exam questions are covered in MENSA. Thus
at least some memory work is needed.

I have three EE degrees (and could readily "qualify" for MENSA);
but I nevertheless studied quite diligently for the Extra exam (2001).
I was gratified to get 100%, but I readily admit taking more than
10 minutes.

Where do you get that, Ralph? That license isn't the final goal. It's
the beginning. If all a person wants to do is pass some test, I suppose
they could memorize Q and A. - although I might postulate that
memorizing over 800 questions for the Extra might be harder than simply
learning the material.

Getting the license is the first goal. You have to memorize the rules to answer many of the questions. Might as well memorize the other parts too. You get your license and you can start to learn about ham radio. Sometimes the questions can be deceiving and what may be a correct answer may not be the "best" answer.

As far as getting good answers about most anything at RAdio Shack or many other stores , what do you expect from someone making the wages they pay ? You do not get a salesman and electronics engineer for those wages. Try going into any store, say Wal-Mart and pick out an area and ask some specific questions about the products and see what they have to say. Chances are you will get the same dumb look and maybe a dumb answer.

One of the reasons this is the only choice we have is that in times past, there were stores which did pay the employees enough to get people who understood the products. People would go in, get their questions answered, then go to the Wal-Marts and Radio Shacks to buy the item because it was cheaper there. We've gotten what we created and what we collectively deserve.

This is getting a bit far from antennas, but the way to know the uncertainty
in knowing time is to have multiple clocks. NBS (whatever it now calls
itself) has a bunch of clocks that are compared to each other.
When I was young (and WWV was back East) the uncertainty indicated from
multiple clocks was a few parts in ten to the eighth power. Today, that
uncertainty is a few parts in ten to the 13th power! It takes multiple
clocks to know the uncertainty.

3769. finally putting copper to the torch for 20, can I make it work for 30 too?

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-26 04:48:55 UTC
From: eternalsquire@comcast.net
Message-ID: <1132980535.219168.49420@z14g2000cwz.googlegroups.com>
Source record: 67466

All,

I'm finally putting together a vertical antenna that I hope will work
on 20 meters.

Soil is sandstone with occasional bits of granite, impossible to drill
into, it has to be
chiseled out with a hand pickaxe. I won't begin to tell you the agony
involved in
chipping out a 2 1/2 foot cubic hole into this stuff, but I managed to
do it.

But in any case forget about soil conductivity, and forget about ground
rods! There
is a single ground rod courtesy of the electrical company... probably
not at good
depth for RF but it is the only game in town.

Construction:

The ground half of the antenna starts with 5 foot of 1 inch diameter
iron pipe,
sunk halfway into hole filled with concrete. 2 1/2 half feet of iron
pipe are exposed
above the dirt. This is connected to 10 foot of 3/4 inch copper pipe.

At the 12 foot level I am mounting 4 radials, 8 foot 1 1/2 inches in
length, of 1/2 inch
diameter copper pipe. I am also mounting 4 copper guy wires, same
length, that are
intended to also work as additional radials.

The radiative half of the antenna starts with 10 foot of 3/4 copper
pipe, topped with
a 9 foot carbon fiber fishing pole. A thin copper wire of about 6 foot
3 inches in length
will be run up the fishing pole, for a total length of 16 foot 3
inches. I will be mounting
rope guy wires on the botttom of the radiative half.

The ground half and radiative half are connected together with a PVC
coupler, and make
contact with each other inside the coupler via a thick styrofoam
spacer.

Question:

This antenna is designed to hopefully work on 20 meters. If I run a wire of 14 feet 4 1/2 inches up the fishing pole instead of the 6 foot 3 inches, and if I use guy wires of 12 foot 2 1/4 inches, leaving the radial lengths unchanged: will I get a vertical that I can work on both 30 and 20 meters?

Thanks in advance,

The Eternal Squire

Here is one little trick I tried a couple of years ago, when I had an elevated 20 meter vertical with the feed point about 10 feet in the air with 4 16 ft radials. I fed it at the base with a 4 to 1 balun, mounted in reverse. I then ran 450 ohm twin lead to the shack with a Johnson Matchbox to tune the feeders..it worked 40 thru 10 meters (some loss on 40 but it did work there ok).
If you try this..you need to do something to keep the twin lead from swinging in the wind..or the impendence will change quite a bit.

Hmmm, I suspect that someone who wanted to learn about ham radio would start that process during the preparations for the test. Those who would want to memorize entire question pools probably won't be too interested in actually learning anything both before or afterward the memorization. As well as not too bright.

> Sometimes the questions can be deceiving and what may be a correct answer
> may not be the "best" answer.

Sure enough. I once took a test in which I was required to answer "the temperature at which solder melts. A through D were all possible answers in this case, because they didn't specify which ratio the solder was. I wrote "E, all of the above" Turns out they "meant" 60/40 solder. So I got the "wrong answer" even though I was a lot more correct than they were.

But that is life sometimes.

> As far as getting good answers about most anything at RAdio Shack or many
> other stores , what do you expect from someone making the wages they pay ?

I expect a correct answer, or "I'm sorry, but I'm don't really know".

> You do not get a salesman and electronics engineer for those wages.

One doesn't need to be an electronics engineer to have an intelligent
outlook.

I've seen it done both ways. And I've seen "rote learners" blossom in
their knowledge and breadth of the hobby after getting licensed that
way. Also the opposite.

Since it is a hobby, what works for the individual seems to be all that
is important.

Support your local hardware store, support your local ham store....

I have paid a slight price penalty plus state and local tax to buy from
my local ham store for almost 20 years. I can also sometimes get break
when I have a rig that needs fixing 3 days before a contest or trip to
FL and the service wait sign says "3 weeks".

Buy local if you want good service from people you know and who know you.

At 14 years of age in 1952, I had little choice except to
mostly memorize the 90 or so general class questions
and answers in The License Manual. Being an amateur radio
operator is what motivated me through a EE degree and a long
career in electrical engineering.

I've recently put up a 140' dipole fed with ladderline. My tuner is separate from my rig, and is an unbalanced unit. So, I use a balun on the tuner output to hook the ladderline to.

I've been told that I should have a voltage balun in this application. I was surprised to hear this, as I expected to hear use a current balun.

Is the voltage balun the right one for this application?

Only if you want your feedline currents to be unbalanced.
Your antenna is a lot like the one described on my web
page below that uses a 1:1 choke-current-balun and needs
no conventional tuner, the most efficient configuration
I could come up with. As can be seen from the current
maximum point graph on my web page, ~100 feet is a good
compromise length for the ladder-line for such an antenna.

A lot of hams will tell you to throw up a random length of
ladder-line and feed it through a 4:1 voltage balun. That's
usually not good advice and often results in a poor balun
function on one or more bands. If one doesn't know approximately
what impedance is being seen by the balun, one cannot predict if
it will function or not. The free version of EZNEC can predict
the approximate impedance seen by the balun. www.eznec.com

Similar to my history. General Class at 16 in 1953. That motivated me
to get (eventually) three degrees in EE. Extra Class came 40+ years
later when I finally wrenched my code speed up to a reliable 20 WPM ..
not that it would matter now :)

Hi,

For 20m I am planning a quarter wavelength vertical radiator with 4
eighth wavelength radials, mounted 12 feet high.

If I add another 4 radials cut an eight wavelength for 30m, will it be
easier to operate on 30?

Thanks,

The Eternal Squire

Doesn't much matter if they are buried radials. I'm wondering
if a short vertical with long elevated radials would result
in an "off-center-fed" vertical.

Cec,

As an aside, there appears to be a little confusion about the various uses of baluns which arises from their uncertain perhaps misleading descriptions.

Because of the way balun winding-wires are run, they are often described as transmission line transformers.

There are --

Voltage Baluns, Current Baluns and Choke baluns.

As I see it, Voltage Baluns have a definite voltage/impedance/turns ratio and are true impedance transformers. They may be used as either balanced-to-unbalanced windings, or be balanced-to-balanced, or be unbalanced-to-unbalanced. Balanced windings may be centre-tapped. One winding may be common to both primary and secondary windings.

Choke Baluns consist of a pair of wires wound together around a ferrite core. The two wires may be of coaxial form or may consist of a twisted pair or just a pair of wires laid alongside each other. The two wires together form a transmission line of calculable impedance and loss.

But a Choke Balun hss no impedance or voltage ratio. It is incorrect to refer to it as having an impedance ratio such as 1-to-1.

A Choke Balun does indeed behave as an impedance transformer from one end of its line to the other. But the transformation ratio is indeterminate. The ratio depends on frequency and line length as with any other transmission line.

The effects of inserting a Choke Balun between an unbalanced tuner and a balanced transmission line to the antenna can be beneficial insofar as tuner settings are concerned.

But in general, the length of line on a choke balun should not exceed 1/8th or 1/10th of a wavelength at the highest frequency of use. This is not too difficult to achieve in the HF range of 1.8 or 3.5 to 30 MHz.

But I do not understand what is meant by a Current Balun.

Perhaps Roy, who is very good at it, could define what is a Current Balun if there is such a thing. And while he is about it, Voltage and Choke Baluns.

He may choose to give them different names. But his views can only be beneficial to the mislading waffle which surounds them.

Reg.

> But I do not understand what is meant by a Current Balun.

Reg, the words, "choke" and "current" have become synonymous
when used as an adjective to describe baluns. A choke-balun
is a current-balun, usually a 1:1. N:1 current baluns exist
where N is not equal to one. Sometimes, an extra winding on
the toroid ensures that the currents are balanced.

> Perhaps Roy, who is very good at it, could define what is a Current
> Balun if there is such a thing. And while he is about it, Voltage and
> Choke Baluns.

Try: http://www.eznec.com/Amateur/Articles/Baluns.pdf

Also: http://www.w2du.com/r2ch21.pdf

Current baluns balance the feedpoint currents and voltage baluns
balance the feedpoint voltages. Since unbalanced currents cause
radiation from the feedline, current baluns are considered
superior for amateur radio applications. The W2DU choke balun is
a member of the subset of current baluns.

Hi ES, How are you going to run the 14' wire up a 9' fishing pole?
I think you would need both the 6' wire and the 14' wire to get dual
band operation. Kind of like a fan dipole for 2 bands.
I think it would be a lot easier to just put up a dual band diople,
and if you could get it up 30' or so it would give a good toa for dx.
But, since you have already dug the hole, I am sure you will stick with
the ground plane.

A choke (or current) balun is the correct choice.

The input impedance of the transmission line to the antenna varies all
over the shop from one band to another. So there is no definite
impedance to which the transmitter is to be matched.

A voltage balun is designed to match between two definite known
impedances of a given ratio, for example 4-to-1, 300-to-75 ohms,
values which never exist at your particular place in the system.

A choke or current balun is not intended to match one impedance to
another. It is intended only to allow, without loss, the transition
from a balanced line to an unbalanced tuner or transmitter.

Because the choke balun is in fact a short length of transmission line
wound on a ferrite core, an impedance transformation does occur
between one end and the other. But what the antenna line input
impedance is transformed to doesn't matter. It is just another
impedance for the tuner to handle and, as likely as not, the tuner
will handle it just as well. Just a change in L and C settings.

Utter nonsense.

There are numerous ways to measure SWR without using a bridge of any
kind.

A bridge implementation is mearly a simple and cheap way to do it and
hence the most likely to be found in use by a hobbiest.

Cec, a choke balun has an indeterminate ratio.

A choke balun which the man asked about, is, as you say, a current balun.

I don't doubt that there are some forms of current baluns which have a definite ratio. But they have more than two wires. They can be used to transform one admittance or susceptance to another. ;o)

One thing for sure - they are all transmission line transformers - for the want of a better name!

In some ways they are remarkable components. They should have been invented 100 years before alongside ordinary L,C, R & G. But they had to wait for the invention of ferrites which I understand did not occur until the early 1940's in wartime Holland. But I would not be surprised if somebody comes along with the idea that the invention was in Bell Labs in the 1930's. Even before the Smith Chart which was an adaption of similar charts in use in the late Victorian Age.

In the 1950's I met an American engineer who told me that in 1945 there were Americans looking round bombed-out German radio factories and by chance came across some tiny top hats with narrow brims and with 3 fine wires sticking out of one end. "What on Earth are these" they asked.

I could go on. It's the Devil which makes me say such things. ;o)

Reg.

Look at your average PC. The cutthroat competition has cause the
typical PC to evolve into a real POS. On the other hand, my G5 Mac is a
piece of art by comparison. And I replace my Macs a lot less than my
PCs. Not to mention I don't cut myself on the sharp edges on the inside
that would destroy the profit margin if they were removed! 8^)

I use both, and I'm not flaming the PC's - just stating fact.

If we want cheap, that is exactly what we'll get.

I'm sorry to say you are all banging your heads against a brick wall.

The so-called SWR meter does NOT measure SWR.

For starters, there is no transmission line on which to measure
anything. Can you find one? It is NOT the one which goes between
tuner and antenna.

To measure SWR on THAT line the meter has to be located in the air at
the antenna end of the line and has to be read using an astronomical
telescope mounted on a tripod. But it would still give the wrong
answers.

Go and think about it some more.

Hi Mike,

If not, it's from "Wal*Mart - the high cost of low prices," a film
(really a DVD) from Robert Greenwald who also did "OutFoxed."

I've been showing the Wal*Mart DVD to audiences for two weeks now.

The social cost to America from Wal*Mart's business practices is on
the order of $1.5 Billion. When you look at if from the Chinese
perspective, they are getting gang-banged too. The presentation
showed how Wal*Mart paid workers 6ï¿½ apiece for an item selling at $12.

It feels that way when trying to discuss SWR with you.

> The so-called SWR meter does NOT measure SWR.

Depends on what you call a SWR meter and what you mean by measure,
but this has already been hashed to bits.

> For starters, there is no transmission line on which to measure
> anything. Can you find one? It is NOT the one which goes between
> tuner and antenna.

It depends on how you implement the hardware to measure SWR, but you
are so obsessed with bridge circuits you have little chance of
understanding there is more in the world.

What do tuners have to do with anything? Tuners are irrelevant to
the original post. Are you deliberately trying to confuse the issue
or do tuners confuse you?

I picked up a new (to me) TS-570S(G) so I can start working six meters. I do not have a dedicated six meter antenna so I decided to try my Fan dipole. It was a 40/80 W9INN dipole that I modified for 18 MHz and 10 MHz by adding two sets of wires. I tried it on 50.125 and rig loves it. I can get full power with whisper of SWR that the TS-570S can easily handle.

The SWR on 51 and 52 MHz is not that good; however, the auto-tuner makes the 570 smile. I am not really concerned as I plan operate mostly at 50 MHz.

Something tells me the 18 MHz wires are semi-resonant at 50 MHz and I got lucky.

As someone who has watched from the sidelines for quite a while, I think
you need to consult a psychiatrist, You really are obsessed over this.
I am not kidding, no shit.

You seem normal in most of your responses, but when it comes to SWR
meters you really do seem to lose it.

50 Mhz is around the 3rd harmonic of 18 MHz, so you basically have a 1.5 wavelength dipole for 50 MHz. Since the 3rd harmonic is normally about 54 MHz, I suspect all the other dipoles are affecting it slightly and the rig likes it. Sounds like a good benefit from those "interfering" dipoles ;)

Doctor Tom,

Hasn't it occurred to you that if most of my responses are normal then there's no reason to suppose my response to so- called SWR meters should be otherwise.

If ever I should feel the need to consult a psychiatrist then I would make arrangements to see one. I would ignore the unqualified opinions of quacks and old-wives on this newsgroup who have allowed themselves to be brainwashed just by the mis-naming of an indicating instrument.

My only reason for continuing with the subject is to provide some education to novices although it seems some of the 'experts' are also in need of it.

If YOU wish to continue with the subject then please say which of my very few earlier technical statements you think are incorrect, and why you think so.

If the discussion should drift towards my personal character then it will be taken as an indication you have lost the argument and have nothing further to say.

Otherwise go QRT

Good replies. Thanks.

So: does the commonly available choke balun (round cylinder with coax connectors on each end, and ferrite beads inside the cylinder) allow us to put unbalanced feed in one end, and get balanced feed on the other?

Or, are they ununs?

3810. Re: is voltage balun right choice?

Newsgroup: rec.radio.amateur.antenna

A properly operating choke (current) balun will cause the currents in the two conductors to be balanced (equal and opposite) at both ports. So I guess you could call it a balbal if you want.

Why would anyone want a device that causes the currents at both ports to be unbalanced?

OK. I read that most excellent article.

I think Figure 21-4 (A) definitively answers my question about the ferrite bead choke balun. Yes, I can put unbalanced feed in one end, and get balanced output on the other.

Thanks again for all the good info.

Since they function by choking RF on the outside braid, they
can function as either baluns or ununs. If RF is choked and
not flowing on the outside braid, then differential currents
are forced to flow in the two remaining conductors be they
parallel wires or the inside wire and braid of the coax.

Your tribander most likely was made by:

Mosley (The TA-33jr had a 12 foot boom & color coded traps);
http://www.mosley-electronics.com/spec%20files/amateur/ta33jr.htm

HyGain/MFJ (TH-3JRS also has a 12 foot boom)
http://www.hy-gain.com/products.php?prodid=TH-3JRS

A W2DU choke would probably eliminate the need for
an RF ground and also be good engineering practice.

I have a 2nd floor shack too, and the antenna is a ground mounted vertical (Butternut HF6V). I use a W2DU choke to connect my coax feedline to the vertical and a 2nd W2DU choke between my Orion and Drake L-4B. Finally, I found that the only way to prevent feedback on SSB was to NOT connect my system to the #8 ground wire that runs out the window sill and down to a ground rod.

A choke balun allows you to go from unbalanced to balanced. If you check Walter Maxwells site and review Chapter 21 (IIRC) of reflections. He gives a test setup that will aid in understanding.

Yep, everyone should realize that a ground wire is N*1/4 wavelength
at certain frequencies, and at those frequencies, is an RF transformer
that locates the standing-wave voltage maximum points at the transmitter. (ouch!)
That's what artificial grounds do - change that *electrical* length
to N*1/2 wavelength. For anyone insisting on an RF ground for an upper
floor, an artificial ground is probably the way to go. I, myself, prefer
balanced antennas and feedlines.

Just starting antenna mod session here in Montana. One is required to have the temp no higher than zero, winds in excess of 30 mph and snowing so that vis is down to a max of 1/4 mile. With those conditions the antenna you erect is bound to be just darn near perfect, why, because you have shown the antenna gods that you are truly worthy.

Dear RB,
I was working on a "linear-loaded" dipole recently. I
got pretty confused
with many, many different opinions. I would suggest that you read
an article in
an 1995 QST about, "How to get the MOST out of your "T" type
antenna tuner"
IF you go to the web site and go to the search engine, you will find
this issue.
I wish that I would have found it sooner. It explained
the "process" very
well. I have photo-copied the article for passing around at my
local club. It is
very good.
Getting on 160m with a very small lot IS a
CHALLANGE ! I've
learned a whole bunch by searching the net. Most of it involves
trying this an'
that. BUT, we all need a place to start.

73's, Paladin

3837. Antennas-History (What's Going On?)

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-27 22:05:08 UTC
From: Wayne Watson <sierra_mtnview@earthlink.net>
Message-ID: <o4qif.1890$Hk1.1683@newsread1.news.pas.earthlink.net>
Source record: 67334

I hardly know where to start with this topic. If one picks up some of the fairly popular (available?) books on the matter, the authors invariably start throwing different types of antennas at the reader, yagi, helical, dipole, folded dipole, parabolic, loop, dish, microwave, quads, etc. For example, I'm looking at an older book on the topic I bought some 20 years ago, The Radio Amateur Handbook by Orr and Cowan. The book is basically for builders. Many such books are. What about the underlying methodology behind this? More generally, here's my question.

I would guess that in the beginning (late 1800s) the simple dipole was it. As years passed, the complexity of antennas has increased. What was the driving force for these changes? For example, how did the inventor of the Yagi (Yagi-Uda) ever dream up the idea for the antenna? Was it the application of theory or did he just get lucky? In fact, is there some underlying theory that drives the design of antennas? For example, the computation of radiation patterns. I'm sure these days the computer would be an aid, but what theory and application drove the development of varied designs before 1960? When did Maxwell's equations seriously get used for this? What suggested a tin can could become an antenna? How did anyone think up the idea of a microwave antenna?

I would think that in the case of antennas that are used for different parts of the EM spectrum a driving force would be the consideration of the wave itself. For example, it would seem unlikely an x-ray antenna (I believe there is such a thing on one of the space satellites used in astronomy) would be anything like one used to receive TV. Certainly the 'antenna' to collect visible light is different than that for AM radio.

Cecil, Don't you mean that when a ground wire is N*1/4 wavelength at
a particular frequency it locates the voltage mininum (current maximum)
at the transmitter, and the voltage maximum well away from the
transmitter. Artifical grounds use a series LC circuit to try and tune
your ground wire to look like 1/4 wave. If they change the
electrical length to 1/2 wave then you would have a voltage maximum
at the transmitter (ouch!).

Why not run two ground wires in parallel -- one twice as long as the
other? When one is Hi-Z the other will be Lo-Z and vice versa.

Nope, Mother Earth dictates the boundary conditions. A well-designed
ground system positions the current maximum point at the ground system,
i.e. minimum impedance to ground.

The voltage maximum point would, therefore, be located at the transmitter,
not a desirable condition. Of course, if you are not actually connected/
coupled to Mother Earth, your milage may vary.

That will help on some frequencies but it is akin to trying to
erect a 1/2WL fan dipole for all frequencies - can't be done. Sooner
or later, you will run into a frequency where length #1 is N*1/4WL
and length #2 is (N+1)1/4WL. "It's not nice to fool Mother Nature."

I thought we were talking about 2nd floor, not well designed ground
systems, with the ground NOT connected to earth. But it is the best
you can do. That is where an artifical ground can help by locating
the voltage minimum at the transmitter.

Yes, that's true. An artifical ground equalizes the voltage
at the ground point AND at the transmitter so both are
voltage minimum (current maximum) points. That's exactly
what an antenna tuner does when feeding a resonant 1/2WL
dipole fed with ladder-line through an antenna tuner. I
hope I didn't misunderstand what you were trying to say.

Let me try to make it easier on you. Why do I have to resort to using an optical telescope to see a star rather than using a radio receiver that might work in the same part of EM spectrum, visual light? After all an EM wave is an EM wave, isn't it? Shouldn't we be able to use the same equipment to observe the entire spectrum? Before I suggest an answer in this case, I'll let you have a go at it.

> What was the driving force for these changes?

Since the beginning of radio, antenna design has been driven mostly by specific needs, to name just a very few examples:

-- By broadcasters to increase their coverage areas
-- By military users:
to increase portability and range
to decrease detectable emissions in some directions
to allow broadband performance for frequency hopping
-- By satellite system designers to concentrate limited energy in particular regions.
-- By cell phone companies to provide coverage to well-defined regions

The list is endless.

Take a trip to your local library and get an index to the I.R.E. (now the IEEE) Transactions on Antennas and Propagation. You'll see that many advances were made in the '20s and '30s in AM broadcast antennas, in the '40s and '50s in aircraft antennas, in the '60s and '70s in satellite antennas. Much of today's development work involves compact antennas for the wireless networks now proliferating.

Antennas provide a limitless pool of tradeoffs involving size, cost, ruggedness, and a large handful of performance characteristics such as directionality, gain, and bandwidth. This pretty much guarantees that new designs will continue to be created.

> For example, how did the inventor of the Yagi (Yagi-Uda) ever dream
> up the idea for the antenna? Was it the application of theory or did
> he just get lucky?

How is any creative design accomplished? How did Armstrong come up with the idea for FM, Watt for the steam engine? I've spent most of my career doing circuit design, and it requires a deep knowledge of theory, but also involves a creative synthesis not unlike what an artist has in deciding what to paint or an architect in deciding what form a building will take.

> In fact, is there some underlying theory that drives the design of
> antennas? For example, the computation of radiation patterns.

You're confusing design and analysis. Design is driven primarily by a need for a particular set of performance parameters. Analysis is done by computation. Analysis is an important part of the design process, in that a design, once created, is analyzed to see if and how well it meets design goals. The design is then often modified and re-analyzed many times until the goal is reached, the design abandoned, or the goal redefined. And yes, indeed, there's solid theory underlying antenna operation.

> I'm sure these days the computer would be an aid, but what theory and
> application drove the development of varied designs before 1960?

Hopefully what I've said above has answered this. A lot more physical modeling and experimentation were required before computers were available, but design was still driven by need, and theory hasn't changed significantly for many decades.

There's no magic computer program that you can put some numbers into and out comes the optimum aircraft design, or bridge, or car, or house. Antennas are no different. Computers can be used to optimize a particular class of antenna (e.g., Yagi or patch) for a particular set of performance criteria, just as they can be used to fine-tune an aircraft or bridge once the basic structure is designed. But not to design an antenna from nothing.

> When did Maxwell's equations seriously get used for this?

They were used long ago as the basis of equations more directly applicable to antenna analysis, and those equations are still used by modern computer programs. In that sense, Maxwell's equations are still being used, although not directly.

> What suggested a tin can could become an antenna?

It's obvious to anyone who understands the most basic of principles. Any conductor can act as an antenna. A tin can is a conductor.

> How did anyone think up the idea of a microwave antenna?

Actually, some of the first experiments with radio waves by Heinrich Hertz were done in the microwave region, so some of the very first antennas were microwave antennas. As for modern microwave antennas, once you have microwave energy (which first became available at high power levels with the invention of the cavity magnetron in 1940), the need for an antenna becomes obvious.

> I would think that in the case of antennas that are used for

> different than that for AM radio.

All antennas obey the same fundamental physical laws. But you're correct that the wavelength of the signal to be transmitted or received plays a big role in determining which antenna designs are practical and optimum. That's just one of the many factors that have to be considered when designing an antenna. All bridges obey the same physical laws, but the optimum design for a bridge crossing a creek is quite different from one crossing the Golden Gate.

In fact, if you change "antenna" to "bridge" in your questions, you'll probably find most of the answers to be pretty obvious.

You did not say what your vertical radiator material is. Make it out of wire (support it with PVC tubing), then you can put up 2 vertical radiators, one for 20m, the other for 30m fed by the same coax. I guess this would be a "Fan Vertical". Its based on a W6SAI design published in 1990. I've done it with 10/15/20m radiators and it works well with elevated radials made from TV rotator wire.

Good luck,

Bill, W4WNT

I'll try to answer that.
Voltage baluns are designed to provide equal voltages on the
outputs, such as those needed for balanced antennas. They help to keep
the balance against external influences, such as nearby metal bodies
and such.
Current balun are used with unbalanced loads, such as windom
antennas, when it's needed to qeep the currents as equal as possible.
This is done in order to minimize radiation from the line, which is
more corrent dependent than voltage dependent.
Choke baluns serve to break the path between the load and the
source so as to prevent energy to flow in a common mode fashion aleng
the line (usually from the load to the source). the name itself-the
full name, that is- " common mode choke" is self explanatory.

Gentlemen:
fFirst of all, stop bickering.
Second, you can't measure SWR. you can measure incident power (going to the load) and reflected power power (coming back from the load). This is done with a 20$ CB type power meter or with a 60 kilobucks network analyzer, doesn't really matter!
You can CALCULATE the SWR using the formula. That, you can do!!!
what we call SWR meter s are actually directional couplers that employ one form or another of phase and magnitude comparisons to separate incident from reflected power and give a relative reading. The measurement itself is meaningless without calibration and the coupler operates in a ratiometric manner, i.e. the output is based on ratios of signals, not their absolute value!

Thanks. Well said. Makes sense to me.
I have a very modest understanding of how antennas work, but from my
simplistic view I just find it a bit odd that if one thinks of an EM wave
shape and content (electric and magnetic) to all sorts of radiation that to
observe much of this radiation different devices are required. From my
underdeveloped perspective, I'd probably trying to design everything with
some wild combinations of dipoles. Maybe I'm thinking of (hoping for) some
grand unified radio or telescope (and methodology) that sucks up any EM wave
one can throw at it. One size fits all. Apparently, we've got a long way to
go on that. :-)

> on that. :-)

The methodology (and perhaps the viewpoint) you are
looking for is... Optics.

From an Optics viewpoint, you're born with two antennas
in your head (that you are using to read this).

From an Optics viewpoint, a hole in a piece of cardboard
is an antenna (an aperture).

From an Optics viewpoint, radio antennas (monopoles,
dipoles, yagis, Sterba curtains) are just minor
peculiarities one encounters when wavelength becomes
"human-sized".

From an Optics viewpoint, we've been at this for an
awfully long time. Maxwell's equations and quantum
mechanics are just frosting on a very large cake. A
great deal of Physics has been devoted to studying
electromagnetic radiation over the centuries.

Unfortunately, the study of Optics is not for the
faint of heart. It leads directly into the heart of
the Physical Universe and things tend to get very
messy, and very mathematical. However, even from
the periphery, the insights are rewarding. Every
time you pick up a camera, you think "antenna".
Every time you see an incandescent lamp, you think
"antennas" (jillions of them). Every time you see
a satellite dish, you think "telescope". And so on...

But of what use is the SWR it after you have calculated it?

To what transmission line does it apply? Where is it? What are the locations of max-volts and min-volts? It does NOT apply to the line between transmitter and antenna. I suggest it exists only in your imagination. ;o)

It is the name of "SWR Meter" which leads to confusion, misunderstandings and arguments. The name says the instrument does something which it does not do. With the help of old-wives, novices are led astray and are stuck with incorrect ideas about standing-waves for the rest of the lives.

Just change the name to TLI (Transmitter Loading Indicator) which is what it is and does very well. The true meaning and associations of SWR will then emerge and all will be flooded with the light of reason.

In particular:
An understanding of how RF reflections can be eliminated
by a 1/4WL series matching section can be had from
understanding how a 1/4WL layer of thin-film on glass can
eliminate coherent light reflections from the surface of
the thin-film. The irradiance equations which predict the
power distribution of light waves undergoing interference
can be used to understand RF energy flow in a transmission
line with reflections. Staring at oneself in a mirror
should convince any skeptical RF engineer that reflected
energy actually makes a round trip to the reflection point
and back and doesn't flow directly from the image-source
to the eye (or to the circulator load resistor). :-)

ml> a equal all band (yeah i know it'd be tall) virticle dipole
ml> (tweeked w/a tuner sgc at feedpoint

The commercial vertical probably uses traps or other means to act like a quarter wave ground plane on all bands. This would be roughly equivalent, performance-wise, to a separate vertical dipole cut for each band.

The issue with using the tuner is that a tall dipole used on a high frequency will throw a lot of energy up at high angles. On 15 and 10 meters, you'd probably rather have a nice low angle pattern. Then again, when those bands are open, you can usually afford to have an inefficient antenna as propagation tends to be excellent.

So, if you're looking to put up something fast and cheap, the dipole and tuner idea can certainly work. If you do that, try to keep the feed line perpendicular as long as you can before it drops down.

Wayne Watson wrote:
"What about the underlying methodology behind this?"

Please refer to the 3rd. edition of "Antennas for All Applications", by John D. Kraus with a host of other professors, for answers to nearly all your questions. Kraus organizes antennas by types.

The dipole is the simplest complete antenna. But, the first practical antenna was patented by Marconi. He was interested in communications over the ocean, so only 1/2 of a dipole is needed. The return circuit is provided by the ocean. Sea water is nearly lossless.

Marconi imagined the antenna as a capacitor plate.. Then he discovered the antenna worked about as well with just the connectng wires inplace, without the plate. As the 19th century turned into the 20th century, Marconi spanned the Atlantic with signals from his antennas.

I think many antenna designs arose as a matter of "necessity is the mother of invention"

For example here is a Yagi antenna quote from URL:

http://ieee.cincinnati.fuse.net/newsletters/200405.pdf

At Tohoku, Yagi initiated a research program in radio-electronics drawing on what he had learned from Barkhausen, Fleming, and Pierce. Other members of the faculty and advanced students, including Okabe and Shintaro Uda, became participants in a collective research effort. A perceived need for better communication between islands and with ships led them to focus on short wave communication with directive antennas. The Yagi group received financial support for the research from a private foundation in Sendai. In February 1926, Yagi and Uda published their first report on the wave projector antenna in a Japanese publication.

For the Cubical Quad see URL:

http://www.antennex.com/preview/Jan501/quad1.htm

Clarence Moore, the station engineer at HCJB in Quito, and some colleagues took along with them a stack of antenna and engineering texts and a Bible on a Sabbatical in 1942. Their urgent goal was to come up with an antenna that wouldn't consume itself by corona discharge when fed with high power, as was happening to their Yagi, at the high Andean altitude of their station. A full wave loop solved the problem.

Some remarkable antenna designs today because of the need to fit an antenna on a cell phone.

For direction finding, loops, interferometers, etc were needed

Hi Reg

I recognize that you know far more about VSWR and measuring complex load
impedances than I do.
I'm writing this to represent the "other side" of an arguement that states
that VSWR *cant* be measured. I claim that VSWR *can* be measured and that
VSWR can be used to identify the impedance terminating the transmission
line.

3871. Beginners Antenna Quest's (for listening only)

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-28 18:45:38 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <4vOdnaymcczQzRbenZ2dnUVZ_sudnZ2d@comcast.com>
Source record: 67368

Hello:

Really new at this, and not really savy on antennas at all.
Trying to learn, but sure is a complicated subject.

Do sw listening only, just about anywhere below 30 MHz. No preferred
direction.
No transmitting.

Presently have a "random length" horiz. wire running around the inside of my
attic. Live in a typical New England colonial.
Goes around the 4 walls, and is stapled every few feet to a wooden roof
support joist.
Probably about 40' x 25' x40' x 25' approximately.

Not connected at the end, so I guess can't be considered a true loop.

Questions:

a. Does stapling to the wood degrade performance ? (wire is insulated)

b. Does the roof degrade performance ? How about when wet ?

c. Would you expect considerably better performance if this exact same
configuration was outdoors, at the same height ?

d. Would it be better if it were soldered back at the beginning, thus
making a true horiz loop (with about a 10 foot vertical run to the receiver
? Why ?

And I guess i should ask: For a single straight random length wire, is the
most sensitivity perpendicular to the wire direction ?
(assuming20 feet off theground, and perhaps 60 feet in length)

Would you expect this to be much better than the indoor configuration I now
have ? Why ?

Is there a good pix on the web showing the lobes for this configuration;
looked, but couldn't find a simple enough one for me to really understand.

Much thanks; appreciate the help,
B.

The tuner SWR meter only indicates the SWR on the 50 ohm coax
between the transmitter and the tuner. However, I have an SWR
meter on the antenna side of my tuner and it does indeed indicate
the SWR on my transmission line.

XMTR--SWR meter#1--tuner--SWR meter#2--50 ohm coax to a G5RV

SWR meter#2 does indeed indicate the SWR on the coax feed to
my G5RV. It obviously does not indicate the SWR at the antenna.

If you are on in a building that has prestressed concrete floors,
and coloums, try using the ReBar in the concrete as your RF Ground.
When I built my house on a concrete slab, before the pour I brought
up a steel strap bonded to the rebar and steel mesh in the radio room.
it was a very effective RF Ground clear down to 500Khz.

Hi Roy -

It's certainly true that a moving charge generates a magnetic field, so perhaps I'm reading it wrong. But it appears to me that Mr. Bailey is arguing here that an electron cannot be compelled to move simply by the application of an electric field. Do you think that is what he is saying? Do you agree?

Jerry, unless you redefine the term "impedance", you cannot generally
measure impedance with a typical reflectometer style SWR meter.

Impedance is a complex quantity (ie with real and imaginary parts).
There are an infinite number of different impedances (being
combinations of the real and imaginary parts) that could cause a given
SWR on a given line in most cases. (The exception is the case when
VSWR=1, you do know the impedance, it is the nominal Zo for which the
instrument was calibrated.)

Whilst you can work out the SWR that will result from a specific
impedance on a specific Zo line, you cannot do the inverse, you don't
have enough information.

==========

The only way to measure SWR on a transmission line is to run a voltmeter along it. At least TWO measurements are needed. Not ONE. And line length is involved.

The voltmeter readings will indeed tell you what the SWR is. But nothing else. It will be possible to calculate from the readings and the distance between max and min what the velocity of propagation is.

But it is essential to add extra critical information before anything else can be deduced. Without this EXTRA information knowledge of the SWR (if it can be obtained) is useless. The so-called SWR meter does not and cannot provide this information.

To calculate the terminating impedances from the SWR it is neccsary also to know the line impedance, its velocity and the exact locations of the max-volts and min-volts relative to the ends. The meter will not tell you.

And the foregoing is on a line which exists only in one's imagination.

I am sorry to repeat, the indications of the SWR meter apply only to the input impedance of the line from the transmitter to the antenna. The meter, in itself, tells you nothing about what is happening to conditions along the line. It certainly tells you nothing about the antenna's input impedance which is of primary interest.

IF, BY SOME MEANS, YOU CAN MEASURE SWR, then there is much more information needed before the performance of the system can be predicted.

The funny thing is - the performance of the system can be deduced from the extra information without reference to the SWR. The whole business is laughable.

Just change the name of the meter and all will become clear.

Reg, G4FGQ.

Here's how I do it, Owen. I modified my SWR meter to tell me
if the voltage sample is leading or lagging the current sample
and if the voltage sample is greater or less than the current
sample. Given the SWR is ratioed to 50 ohms, that's all I need.
I adjust the length of my feedline until I find a current maximum
point and the rest is easy.

==========

Cec, you are not telling the whole truth.

The meter tells you nothing about the important main G5RV transmission line. ie., the SWR on the ladder line between the end of the coax and the antenna. Neither can it tell you what the antenna input impedance is.

There are other ways of finding the input impedance of the G5RV antenna and its effect on line SWR if you should ever be sufficiently interested. You could use a computer program. ;o)

Reg.

<snip>

Probably as well put as I've ever seen it and absolutely true.

Look at antennas such as Log Periodic, Slot, Turnstile. The design
Initially required more creative juices than engineering know-how. The
engineering came after they were visually created in the mind. I know
that to be a fact with the slot antenna. Some of the best engineers I
have known, are those who visualize the function and then confirm it
through calculation and measurement. In my opinion, these people are
more like artists than engineers.
For example, many people can put paint to canvas technically however,
only an artist can use the paint to create what appears to be a living
thing. The same holds true for engineers. The capable ones have the
knowledge base. However, the really really good ones have something
extra which is learned from books. Those are the special ones, the
inventors.

Nice try Cecil.

Note Jerry's statement: "VSWR can be used to identify the impedance terminating the transmission line".

Your method, impractical as it is, means you have found a point where the impedance at the instrument terminals is purely resistive, and a minimum, and you are correct that you could calculate the value of that resistance. That measurement does not tell you the "impedance terminating the transmission line" unless the line is of zero length. You could make another measurement with another instrument (line length using a ruler) and using other knowledge, calculate the "impedance terminating the transmission line".

In a practical situation, there is a risk that there is current flowing on the outer of a coaxial line or unbalance current in the case of an open wire line. In that case, changing the feedline length may affect the load impedance at the end of the line, so your proposed method may alter the very thing you are "measuring".

Knowledge of the SWR AND the position of the standing wave pattern wrt the load AND the loss characteristics of the line is enough information to determine the "impedance terminating the transmission line"... but a typical reflectometer SWR meter does not measure all of those things.

If you know the forward and reflected power, VSWR can be calculated as
follows:

VSWR=(1+sqrt Pr/Pi) / (1-sqrt Pr/Pi)

I believe.

Cec, That's a calculation, merely arithmetic, not a measurement.

It applies only to a long line lossless line which does not exist but
Zo must be 50 ohms. And nobody has the foggiest idea where max-volts
and min-volts are located. And so the calculated information is
useless except for trolling on newsgroups. ;o)

Here are several VSWR measurement techniques. They are real they are
valid and I used them for years. VSWR is a *very* important parameter,
especially when dealing with high power systems.

Hi Reg, Do you advocate changing the measurement and calaculation that all our handy little Antenna Analyzers report as SWR to TLI? That would cost a lot to re-tool. My MFJ-259, and I think you have stated that you have one also, reports lots of useful info, and uses a bridge, a PIC, and a neat display. SWR as well as many other parameters are measured indirectly, and calculated with the Micro. You could make the agrument that all the other stuff the Analyzer reports needs to be more descriptive, but it would cost too much to change. If you read the manual, and know what the displays on any meter really means, then why change anything?

A transmission line transforms the impedance in a predictable
manner given the transmission line specifications. One can
backtrack the SWR spiral on a Smith Chart to get a reasonable
estimate for the antenna impedance. The impedances for my dipole
calculated in such a manner are pretty close to the ones predicted
by EZNEC.

> In that case, changing the feedline length

The load impedance is what it is, virtually unaffected by
feedline length.

> ... so your proposed
> method may alter the very thing you are "measuring".

Virtually every time one makes a measurement, one alters the
very thing that one is measuring. That's just a fact of life
and not a valid reason to give up trying to make measurements.

Let's say we have the following system configuration with
a 1:1 choke at '+':

100W XMTR---50 ohm coax---+---300 ohm twinlead---...
Pfor1=100w--> Pfor2-->
<--Pref1=0w <--Pref2

What's the forward power on the 300 ohm twinlead?
What's the reflected power on the 300 ohm twinlead?
What's the SWR on the 300 ohm twinlead?

Hi Reg

I have no understanding of why you find it important to state things that are not true about VSWR. VSWR *can* be measured. It is clear to me that you know that the Complex Impedance terminating a transmission line can determined by measuring the VSWR. Sure, it requires the position of the voltage mins (or maxs) be identified, with the load and then with a short ckt., and a Smith chart to be used for quick/easy identification of the load impedance. But, is that so much calculation that you find it necessary to state " IF, BY SOME MEANS, YOU CAN MEASURE SWR, then there is much more
> information needed before the performance of the system can be
> predicted".

The load impedance isnt "predicted". It is actually *determined* with an accuracy associated with the precision of the test equipment.

I consider measuring VSWR on a transmission line to be an excellent method of determining load impedance.

To do that, you need to determine the position of the standing wave pattern with respect to the load, and a typical reflectometer style SWR meter does not do that. You could put a ruler to the line, but you are using another instrument to make a another measurement that the reflectometer could not make.

It is misleading to suggest that a reflectometer style SWR meter alone is useful for determining the impede dance of a load connected to the meter by a length of transmission line, save possibly the case when VSWR=1 and the line is low loss and Zo is the same as the calibration Z of the SWR meter.

Yes it does, if one has the ability to vary the length of the feedline
until a current maximum point (minimum SWR) is known to be located at
the balun/choke. I do it everytime I get on the air. That's how I tune
my antenna system and I don't use any conventional tuner at all.

> It is misleading to suggest that a reflectometer style SWR meter alone

Not misleading at all. I do it all the time. I know the exact length,
velocity factor, and Z0 of my feedline. I know an SWR current maximum
point is located at my choke. I know if it is greater than, less than,
or equal to 50 ohms. It is a rather simple-minded process to accurately
estimate the antenna feedpoint impedance given everything I know. You
should try it sometime. Even if I didn't know if the current maximum
impedance was lower than or higher than 50 ohms, there would only be
two possible antenna impedances. EZNEC has a perfect track record in
predicting which of those two antenna impedances actually exists.

Cec,

The meter indicates SWR on the 50-ohm coax between meter and transmitter. It HAS to be 50-ohm coax. Any other impedance and you get the wrong answer. Without measurement of Zo = 50 ohms it can only be assumed.

You then include in the calculation the measurement or assumption of the Zo of the 50-ohm coax, and the measurement or assumption of Zo of the twin-line, and the forward and reverse powers, and the SWR on the twin line can be deduced or assumed.

But if you think you are measuring SWR on anything you are cheating and fooling yourself.

In your particular case an assumptiom of Zo = 450 ohms for the twinline would be very much in error because both you and I know you have measured Zo to be 380 ohms. I can tell you what the SWR is on YOUR feedline without getting out of this armchair. I don't need to know your meter readings. ;o)

==========
Jerry,

It is important because the SWR meter is EDUCATIONAL. It is more than a pair of red and green LED's on our automatic tuners.

All along I have stated that the name of the so-called SWR meter should be changed. Other more technical statements have been made to convince they whose state of mind prevents agreement.

Remarkably few people disagree with my technical statements but offer no reasons for disagreement or prove me to be incorrect.

SWR meters are by far the most prevelent topic on amateur radio newsgroups. It appears time and time again in contexts which demonstrate it to be a source of misunderstandings, arguments and general confusion.

I maintain that the instrument's name is the root cause of the problems. It does not do what its name says it does. This inevitably leads people, not just novices and CB-ers, into incorrect channels of thought which become deeply ingrained. It unnecessarily introduces SWR into discussions which actually have nothing to do with SWR. And worst of all, when operating equipment, it causes people to have problems which either don't exist or are different to what people imagine they are. Mis-education is the keyword.

Re-naming should begin in amateur radio handbooks and similar publications. Editors should be the first to be educated.

SWR meters are seldom mentioned as such in professional text books. They are given other more correct names. Terman manages very well wthout them. But there's nothing wrong with his bibles. (Yes, I know they probably hadn't been invented in his day.)

Perhaps when our Chinese friends enter the amateur radio market, manufacturers' wisdom will allow the light of reason to shine through. But they will have to get a move on. I can foresee the time when automatic tuners are universal and the only meter on black boxes will be the S-meter.

I don't doubt that you thoroughly understand how the so-called SWR meter works. But even the present discussion is enough to demonstrate that a simple change is needed. In the end it all reduces to economics and survival of the fittest argument.

Gerry,

The load is the antenna - about which the SWR meter knows absolutely nothing. All the the meter has to work with is the input impedance of the tuner or the transmission line.

Line input Z = R+jX and to aggravate matters the meter discards all information about X.

Reg.

Well, it's obvious that an electric field can move an electron. The Lorentz force law tells us how much force results from a given E field, and we can get the resulting acceleration from Newtonian physics. An everyday example is an oscilloscope deflection system which uses an electric field to deflect electrons. (Actually, modern digital scopes typically use raster displays with magnetic deflection -- but many of still have older analog types with electric field deflection.)

But if the antenna conductor were perfect, no E field at all could exist at the wire surface regardless of the amplitude of the E field of the

oncoming wave. The wave's E field therefore couldn't directly influence the electrons in the (perfect) conductor. Only the H field of the wave, then, can induce a current in the perfect conductor. The direct influence of the E field on an imperfect conductor would be highly dependent on the conductivity of the wire, and I'd guess it would be very small compared to the influence of the H field from a typical oncoming wave on an electron in a good conductor. Maybe that's what he was saying.

I bought this antenna on a 30 day trial, and just got it about 12 hours ago. So far I'm not at all impressed. I live about 150 miles from an AM station, at 810, in the SF/SJ Bay Area, which has a marginal signal, but usually listenable. Putting a new PSU in a PC about a month ago increased the noise in AM radios 70-100' from the PC to an almost unacceptable level. I had hoped the antenna would boost the signal enough to knock down the noise. There are times when I can get a good signal from the station, but certainly less frequently than before.

The antenna consists of three parts: a 600-1800 KHz control dial, a ferrite antenna and something called the antenna element. The latter is about 8" long by 3" by 1.5" (high). The idea is that one puts the ferrite antenna very near the radio and the antenna element in some other spot, then adjusts the control dial to the max strength. I detect zero change in any AM signal from the (C. Crane) radio anywhere on the dial. The antenna element can be grounded. I modestly did this by hooking a wire (alligator clips) from the element to the ground socket of an AC outlet (nail in the socket). No change. BTW, when I was doing the experiment last evening, the signal was pretty decent during that period. In fact, quite listenable. All this without the device though.

I'll continue to experiment, but so far not so good. Comments?

I hope you now see the advantage of being able to vary the
length of the ladder-line until a current maximum point is
located at the choke-balun. Knowing the impedance is purely
resistive and relatively low allows me to read it with my
MFJ-259B. That resistive point is on the ladder-line SWR circle
on the Smith Chart. An arc of the SWR circle is the known length
of the feedline which gives me the feedpoint impedance of the
antenna (and can be adjusted for losses).

Actually, nowadays I use my MFJ-259B to read the resistance at
the choke-balun where I have adjusted the ladder-line length to
guarantee the existence of a current maximum point. It's actually
easier to do than to write about it. An assumption that Z0=50 ohms
is not necessary.

> But if you think you are measuring SWR on anything you are cheating
> and fooling yourself.

I actually have an SWR meter calibrated for balanced 380 ohms but it's
in a box somewhere in my garage. I found my indirect measurements to
be entirely accurate enough. In general, if one can isolate the problem
to 10% of the Smith Chart, one can solve any problem by tweaking.

Speaking of indirect measurements - let's say the feedline Z0 is 380
ohms with a VF of 0.9 and a length of 90 ft. The measured resistance
at the current maximum point is 30 ohms on 7.15 MHz. The SWR on the
ladder-line is 380/30 = 12.7:1. The feedline is 0.727 wavelengths
long. Plot the point 30/380 = 0.079 + j0 on a Smith Chart. Draw an
SWR circle through that point. Backtrack from that point around the
circle for 0.727 wavelengths and there's your antenna feedpoint
impedance (neglecting losses). Losses can be taken into account by
using SWR spirals instead of SWR circles. And of course, all of this
is done by a computer program after just a few seconds of data entry.

From: Jeff Dieterle <jdieter@nospam.carlnet.org>
Message-ID: <11oos4qo1fo1dd2@corp.supernews.com>
Source record: 67315

I'm inside an office inside an old brick and steel factory and can get very little AM reception, only a few of the stations located in the same city. I ran RG6-U coax to the roof of the factory (appx.100ft) and considered buying a loop antenna but at this groups suggestion connected the coax to a long wire. The stations I'm interested in are Indianapolis 1070kc and Chicago 670kc & 1000kc. I installed 200ft of #12ga insulated wire that is orientated in line with these 2 cities and 6' above the roof at the terminations and 3-4' in the center. I grounded the coax shield at the roof and in my office and I'm using a GE Superadio III on batteries. I can get these stations fine in the daytime with a reasonable amount of static but at night the static increases severely. Is there anything else I can do to make this a better antenna.

Thanks in Advance
Jeff

I think that was probably used to describe the Bird which,
to the best of my knowledge, has no SWR scale on the meter
face.

Now my Autek WM-1 actually has an "SWR meter" on the front
panel in addition to the "watt meter". I don't use a tuner
and it computes the actual SWR on the RG-213 going to my G5RV.
I achieve an SWR very close to 1:1 on the RG-213 on all HF bands
by varying the length of the balanced series section. 36 feet
of ladder-line works for 40m and 17m, my two favorite bands.

It was around 1949 when I started hanging out at W5OLV's
shack. He had a homebrew 1625 transmitter with a parallel
tank circuit. The plug-in tank coil had a few turns of wire
wrapped around the bottom and that was the transmitter output.
He didn't use a tuner. He had a pickup loop that he slid up
and down the line until he located a current maximum point.
He cut the line at that point and fed it directly from the
transmitter. He added or subtracted turns on the plug-in coil
until he was satisfied. I didn't really understand what he was
doing until I studied the Smith Chart in college almost ten years
later. I now use that same basic technique with my 50 ohm
SGC-500 amplifier.

Roy, W7EL wrote:
"But, if the antenna conductor were perfect, no E field at all could exist at the wire surface regardless of the magnitude of the E field of the oncoming wave."

If we have a non-varying E field, a perfect conductor in the field would have the same voltage everywhere due to the short-circuit connecting all points.

But, an electromagnetic wave sweeping the wire has an alternating electric field. Its phase is uniform (the same) across the wavefront because all points are equidistant from the source. A wire parallel to the E vector would simultaneously experience the same E field force throughout its length. "No E field at all could exist at the wire surface regardless of the magnitude of the E field of the oncoming wave,"

Why must the wire be perfect?

Best regards, Richard Harrison, KB5WZI

I'd change the power supply to a better brand.

Generally if you have atmospheric or man-made noise increasing the antenna efficiency is just going to increase the noise along with the signal.

You could try to make a directional antenna; this would increase your desired signal more than your noise.

The antenna would have to be big, however. The wavelength at 800kHz is somewhere around 370 meters and you'd need to use around 1/4 of this.

You could try to feed power supply noise to the radio antenna at just the right amplitude and phase to null it out. This would be a good subject for an undergraduate or even a Master's thesis in EE but probably not a good thing to do in practice.

You could attempt to shield it. Rat Shack has some clamp-on ferrites, you could put one of these on your power cord close to the end that plugs into the power supply. You could also make sure that the PC case is well shielded.

Naw Reg, I dont have the slightest idea how a "VSWR meter" works. I was too quick with my response about the worth of VSWR. I thought the discussion was aimed toward the VSWR itself.
I've got to re-read that story about Silence is Golden and put it to practice.

It could be what he was saying. But conductors are are called
conductors for a reason, and it's not necessarily because they conduct
magnetic fields well.

Dear Group,
I have two "main" antennas that I use in my small
lot. About 1/8 0f an acre
or say 70ft. wide by 140ft. deep. There are utility lines on one
side of my property.
One of the antennas is a full-wave loop for 80m. It is up about
30ft.,and feed at the
feedpoint by a 4/1 balun into good coax to the shack. The other
antenna is a dipole;
140ft long feed by ladderline to the shack. I have a tower(60ft)
and a couple of small
uhf and vhf beams also.
My question IS how are the near-fields and the far fields
INTEREACTING with the other
antennas ? What does one antenna DO the the transmit or recieve of
the other ?
How close can these antennas be to each other? What problems will
I get because
there is NOT enough space inbetween the elements ?

You never mention how far away you are from "... Indianapolis 1070kc and
Chicago 670kc & 1000kc." That'll have a LARGE bearing on the day/night
reception question.

The 'noise' is _also_ a signal -- just one that nobody wants to receive.
The "C. Crane's Twin Ferrite Antenna" happily 'improves' the reception
of the noise -- in addition to the signal(s) you desire.

Let me guess: That PSU was "Made in China".

Any rf noise put out by the computer ps is going to be picked up by
your antenna as well as the radio station you are trying to hear. So a
better antenna (if your new one is indeed better) wil just pick up
stronger power supply noise. It's moslty a null situation.

What you need to do is get that power supply fixed or replaced

A time-varying E field can exist in a non-perfect conductor; it cannot exist in a perfect conductor. You can find the explanation for why this is in any electromagnetics text.

Interesting. During the PAQSO party we had a similar situation as we
were operating 2 stations simultaneously.

As far as I know, the answer is "not much" on transmit. Less on
recieve. Now if you are trying to use both stations at the same time,
there can be a lot of problems. Our antennas were a tribander used on 20
meters, and a 40 meter dipole. We were both running power, and the 40
meter station was reaking havoc with me on 20 meters. I made a stub to
put on the 20 meter rig, and all was harmony.

The distance from the dipole to the tribander was areound 40 feet at
closest rotation angle.

>What problems will I get because there is NOT enough space in between the elements ?

Do you mean on the beams?

That's certainly a context where an E field is always accompanied by an H field. But the statement as it was written is nevertheless untrue. That was my only point.

> Is it possible for an RF E-field to
> exist without an RF H-field?

Seems to beg an obvious answer. But the question brings up a point that people seem to be missing here. An E field is an E field - there are not different 'kinds' of E fields. The field itself is the same, whether it varies in time or not. A non-zero dE/dt allows for some of the more interesting properties to have non-zero solutions, but the fields themselves are not unique. I hope that concept isn't too controversial for this group. If it is, I will strive to keep such ideas to myself in the future.

Non-virtual photons, as opposed virtual non-photons I presume. I think physicists know they're going to have to wait until they get to the pearly gates before they can really learn what "electric fields are made out of". ;-)

Cecil, you have a single solution, and you are inclined to transform every problem to require that single solution (read your posts).

Whilst step variable length transmission lines have application, they are not the solution to every problem, or indeed, to many problems. You are not the originator, nor the only user of such.

Since you mention the Smith chart, you are a champion of operating transmission lines at very high VSWR, and yet would suggest that a Smith chart can give you an adequate solution for the losses. That says more of what you consider adequate than the suitability of the Smith chart as a solver of that type of problem, especially in this day and age. I suggest that the Smith chart loss solution is adequate when you can ignore the losses.

I can visualise you sitting amidst an expensive heap of inch size pieces of LDF5-50 and a Bird 43, slide rule and Smith chart, with a caption "It is possible, and it is practical!".

Yes, you could say that I understand the advantages of a step variable length transmission line. It is probably why they are used as much as they are.

A static E field can exist alone but to detect it requires something
like a field-mill which basically converts it into a changing EM field
that can be readily detected. A simple field-mill is basically a
rapidly spinning antenna. Relativity at work.

I wonder if it would help putting up a short vertical and summing its
signal with such polarity that it cancels the noise from the main
directive antenna? This on the theory that most man-made noise is
by its nature vertically polarized.

Sorry, I just got a new Dell and don't have my software loaded.
A quick pencil whipping of a Smith Chart graph yields a
load around 1140 - j1900 ohms which would be about right
for a 145 ft. dipole on 40m.

No, my solution allows me to pull Reg's leg in arguments about
SWR meters since I don't use a tuner. :-) My solution also allows
me to get by without a 500 watt tuner for my SGC-500. The other
advantages are just frosting on the cake.

Reg, G4FGQ wrote:
"It is impossible for an E-field to exist without an H-field."

Agreed.

By definition an electromagnetic wave includes an electric component and a magnetic component. That does not mean the components are inseparable.

The purpose of a Faraday screen is to eliminate capacitive coupling while permitting magnetic coupling.

I`ve worked in several medium wave broadcast plants. In these, each tower was coupled through a 1:1 air-core transformer to its transmission line. The transformer consisted of two identical coils, one on either side of a Faraday screen. The coils shared a cmmon axis.

Electrically, the transformer was transparent at the transmitting frequency. It coupled the transmitting frequency as if the transformer did not exist to impede. Its purpose was to eliminate capacitive coupling, The Faraday screen provided a place where electric field lines are shunted to ground.
The problem with capacitive coupling between a transmitter and a tower is that the higher the frequency, the less the reactance or opposition. The coupling is better through a capacitance to the harmonics of a frequency than it is for the fundamental. The Faraday screen removes this unwanted bias for imroved harmonic propagation.

A side effect of the Faraday screen is that it removes lightning strokes before they reach the transmission line from the tower.

The Faraday screen looks like a metal rake. Its back where the teeth or tines join is firmly grounded. The teeth are open-circuited. Current cannot circulate between and through the teeth, so no counter electromotive force can be generated to oppose magnetic coupling between primary and secondary coils. The rake is transparent for magnetic coupling but it is a stopper for electric coupling.

By complete shielding, that is metalllically enclosihng one or both coils of an impedance coupling pair, magneric coupling between them can be practically eliminated. A coupling capacitor between the coils allows only the electric field to be effective. There`s no magnetic field involved.

I`m no advocate of the E-H antenna, but the electric and magnetic components of a wave are easily separated.

Best regards, Richard Harrison, KB5WZI

You didn't differentiate between the lossy and lossless solutions. The difference isn't very much, I figure about 1100-j2000 vs 1000-j2170 which is real hard to resolve on the Smith chart. Smith chart programs solve the same tranmission line problems as underlies the Smith chart, but using a program provides much higher resolution, and the convenience and accuracy benefit of not having to find the solution in a normalised domain.

The Smith chart does not directly indicate the mismatch loss in the general case.

My online calculator at http://www.vk1od.net/tl/tllce.php produces an answer (considering loss) of 422.87-j1441.91 if the transmission line was 90' Wireman 552 and using Wes's characterisation of 552 for derivation of the fundamental line parameters (slightly different Zo to yours). Indicated line loss is 0.93 dB. (SWR is not used to arrive at the solution.)

Dan's TLD gives 432.7-j1459.0 using a slightly different transmission line approximation, and independently deriving the model from Wes's characterisation. Indicated line loss is 0.93 dB.

This demonstrates the sensitivity of the result to very slight variations in line parameters, consideration of loss, and the approximations used in modelling.

Owen

Hi Owen

Did you mean to write the load impedance as 0.079 + j0? Or did you mean
0.079 + j1?

As others have said, you should try to attenuate the noise at its source. If it is radiated, you need a better PSU. If it is coming out on the PCs AC line, line filters might help.

If the PC and KGO are not in the same direction, some sort of directional antenna might help.

Of course, the ultimate solution would be to move to SF and get a really big signal. But there are problems with that, too: I live abt 3-4 miles west of KNX (50 KW, 1070 KHz) and my problem is avoiding it, not making it stonger :)

I'm afraid your Faraday screen might not work quite like you think it does.

In the vicinity of the screen, the E field is indeed reduced. However, you haven't stripped off the E field from the EM wave, or separated it. The E field is largely reflected from the screen, but out of phase with the original wave. So the E/H ratio is smaller on *both* sides of the screen. Close to the screen, much of the energy formerly in the E field has been transferred to the H field. But as you go beyond the screen in either direction, you'll find the E field increasing and the H field decreasing as the energy redistributes itself. Within a short distance (typically considerably less than a wavelength, but depending on the size of the screen), the ratio of E/H will again be close to 377 ohms, assuming air is the surrounding medium. The Faraday screen works in the broadcast application only because the "shielded" component is close to the screen, where the E/H ratio is low.

In other words, you can modify the E/H ratio in a small region of space by moving the energy from one to the other. But you can't separate the two components or eliminate one or the other.

This is of course referring to time-varying, not static, fields. Reg's statement is technically false, since he didn't say whether the fields are time-varying -- static E and H fields can independently exist. But time-varying E and H fields, which I'm sure is what he meant, can't.

Roy Lewallen, W7EL

It's similar in some ways to a method for detecting magnetic fields used prior to the advent of Hall effect devices. Not sure how it relates to relativity.

Perhaps it's true that an electric field is simpler create than to detect by direct means. But it isn't really any more difficult than, for example, measuring power by direct means. I think Ben Franklin measured the E field in a Leyden Jar by calibrating the leaf displacement caused by the Coulomb force resulting from the electric field between the two similarly charged surfaces.

3956. Stacking Satellite VHF and UHF F9FT Antennas

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-30 00:41:40 UTC
From: alain@alain.it
Message-ID: <1133311300.421664.127270@g44g2000cwa.googlegroups.com>
Source record: 67203

Hello all,

I actually own a 2x9 VHF and a 2x19 UHF by F9FT (Tonna).
Since I need better performance (especially on VHF) for LEO operations
I was thinking about stacking another antenna identical to the one I
already have.
The suggested stacking distance is 2.77 m. Since I am doing this
upgrade I tought about stacking another UHF antenna too so that I would
have an horizontal mast 3 meters long, with the VHF yagis at the ends
and the UHF yagis in the middle.

I have some questions:
1) Will the UHF yagis create troubles to the VHF since they are in the
middle?
2) What kind of real performance increase will I experience on VHF?
3) Can I couple the vertical elements with a coupler and the horizontal
elements with another coupler and then apply a RCHP/LCHP coupling
harness like I would normally do on a single antenna?

Thanks

Alain De Carolis

When I turn the computer off, the radio station noise drops dramatically. It doesn't matter if I use AC or DC. I can detect the large noise change in my car from the garage.

I tried the RS ferrites and they made no change. I even took barbell weights
and put them on the AC line of the PC. Zippo. If I hadn't already spent $60
for the new PSU six weeks ago, I might think of buying a much better one.

In some way this may be circuit dependent. I do believe I plugged in my
other PC to the same socket and had the same experience; however, when it's
plugged into its normal socket, there is no noticeable change.

Interestingly, bad weather moved in yesterday and today, and reception from the station has been quite good with the normal antenna. This stuff can get pretty strange.

Yes, you absolutely guessed the right country. I called the tech support and
they were less than useful. I asked about a circuit diagram. Sorry, we don't
have one to give out.

The trick here is that I see absolutely no change at all. One would think
maybe the volume might increase, but nay.

I think the only solutions to the PSU problem is to buy a much better one.
As I mention above, that's probably a losing proposition. I doubt after 6
weeks they would take it back. It might be worth a try though. Note my
comment above to someone a few moments ago that this seems to be a household
circuit dependent problem. Another PC in the same room works fine until I
plug it into the socket that I first noticed the problem.

Yes, I've had that experience with close stations. You can probably listen
to it through the bed springs. :-)

Attempts to shield the AC with the RS ferrite block and a barbell weight
failed. See comment about household circuit dependency in my just posted
responses above yours.

Ferrites clamped around the power cable will help with common-mode RF
noise. They won't do anything to help cancel out differential-mode
noise.

It'd probably be beneficial for you to try to get a robust powerline
noise filter. These will filter out both common-mode noise, and
differential noise as well.

Unfortunately, it's possible that the new power supply is radiating RF
directly, rather than feeding it back into the mains. If so, nothing
other than replacing it, or switching to a PC case with better
shielding, is likely to help the problem.

Hmmm, just maybe, you might be able to ditch it as a warranty item.
Dunno tho' as it will depend on the outfit that sold it to you. I don't
know if you are a Ham or not, but if you are, you might play the part 15
card, as they are required to not interfere. I suspect that a 160 meter
rig might catch the same interference.

It is kind of a drag though, since IIRC a noisy switcher Power supply
is hard to fix. Good luck!

Wayne,
You may wish to get one of those $5 circuit analyzers from your local
Lowe's/Home Depot/Tools R Us (yes, I realize this probably means a
drive to Grass Valley) and check for open ground connections on all
your sockets. I had grounding issues at my home and after getting a
shock while adjusting the hot water in the shower brought in an
electrician. He found many problems such as the hot and return
shorting on the bathtub (behind the wall of course where it can't be
seen) and most of my outlets did not have a ground. Had the house
re-wired and it got a bit more RF friendly - hope you find your issue
and don't have to rewire the house.

BTW, Nevada City is a nice place to call home - if you bump into
Mayor Arnett tell him that Howard from LA says hi.

Howard

> noise.

Differential mode radiation is almost never a problem in situations like this. The differential mode component of the noise, by definition, is from equal and opposite noise currents on the two conductors (of the power line, for example). For this mode, the conductors comprise a transmission line, and radiation will be extremely small because the fields from the two very close and parallel conductors are equal in magnitude and opposite in direction.

Ferrites are a good suggestion, but the ones commonly used for RFI suppression are of a ferrite type which doesn't have an awful lot of attenuation as low as the AM broadcast band. Best would be some Fair-Rite 70 series, or other ferrite with an initial permeability of several thousand. Best would be to get a large core and wrap multiple turns on it with the power cord, as close to the PC as possible. This way, you get a lot more impedance than clamping cores onto the wire, since the impedance is proportional to the square of the number of turns. That is, 10 turns on a single core gives you the same impedance as 100 of the same cores clamped onto the cable.

> It'd probably be beneficial for you to try to get a robust powerline
> noise filter. These will filter out both common-mode noise, and

A good power line filter isn't a bad idea, but differential mode filtering won't make any appreciable difference.

> other than replacing it, or switching to a PC case with better
> shielding, is likely to help the problem.

To radiate any significant amount of energy requires some sort of antenna, so a power supply won't radiate much on its own. The trick, then, is to prevent the noise from getting from its source to the antenna. The most likely antenna is the power line, but any other wires connected to the computer can also serve this function. I'd start by disconnecting everything from the computer except the power line, getting the noise down with ferrites or a power line filter, then connecting one thing at a time and applying ferrites to the other wires as required. If wires inside the computer are acting as the antenna, the computer box should contain the noise to a high degree -- if you still have noise with only the power line connected and filtered, check the integrity of the computer case. Look for any seams that don't have good metal-to-metal contact between pieces.

<wolf_tracks@invalid.com> wrote:

>If so, how do I track it down?

Hi OM,

You have already related other experience where you shared the same circuit as a noisy source (sharing the same circuit is easily identifiable as being on the same breaker). Moving to another circuit can be a solution. If it provides relief, then noise was coming by conduction (through the wires) rather than radiation (over the air).

Insofar as your specific weather related symptoms, this is usually related to a loose and corroded ground connection. The first place to start is with your panel's service ground. If you have other ground rods, then check them and INSURE they are also connected to the service ground.

In your shack, do not daisy-chain grounds - use a star configuration. However, you will probably still have mixed grounds with equipment interconnections (and some of them are obvious and in your face and are still invisible). That is OK if you also have the individual equipments grounded in that star configuration. One of those invisible gotchas is the equipment interface to a computer, with a dial-up modem, its connection to the phone line and its own ground (if in fact it exists). This ground path is one you stare at every day and never see - unless lightning is looking for ground in through it and into your shack.

To "track it down" requires that you pull every plug, break every breaker and listen (you will need a battery powered, ungrounded receiver that exhibits the problem to do this). Replace each one at a time until you re-achieve your problem - take one step back and focus there.

Heh heh. I remember one time a friend of mine was wailing that his fancy new outdoor 2m antenna wasn't working as good as the indoor mag-mount on a pie plate that he had been using.

I asked about his installation and he informed me that the antenna was properly installed and that the SWR was 1 to 1. So I inquired further. He was using a bridge to measure reflected power at the transmitter. And there really wasn't any. Then I asked him what he was using for transmission line. Turns out it was about 75 feet of cheap RG58. So I told him to take it off the antenna and see what the bridge said with no antenna. It climbed all the way to 1.2 to 1. In short, the coax was simply eating the power. Changing it out to better quality line proved to be the answer there.

SWR is so overrated. I'm in the process of putting together a modest balcony-based HF station. I'm much more interested in the efficiency of loading coils than in actual SWR on the coax. A 3-to-1 SWR on coax is meaningless at 80 meters. It adds only a fraction of a decibel to losses, even in RG58. But your transmitter might not like the complex load it is seeing at the end of that coax, hence the utility of a tuning device. Back in the day, I used to just ignore such issues because my transmitters had pretty good output tuning networks. But with the advent of broadbanded solid state finals, it is necessary to match the radio to

the transmission line's complex input impedance.

Saandy,

You are a man after my own heart.

I would further simplify it. No need to mention SWR. It is
meaningless. Just make sure the transmitter is loaded with about 50
ohms and leave it at that.

To make things nice and tidy, just change the name of the meter to TLI
= Transmitter Loading Indicator.

Some of what you say is very true. Especially in the world of HAM radio. How ever, this being an open forum, truth is of great importance. Your thesis on the "whys" of the importance of vswr measurements are incorrect in some areas.
Yes, importance grew with the advent of coaxial lines simply because of the relatively small distances between inner and outer conductors. That part is true.

However, until you've seen a 6" universal coaxial transmission line with no insulators or inner conductor remaining over a 350" run, I guess you can't really appreciate the need for monitoring and maintaining good "system" vswr characteristics.

Now to the measuring of said vswr. It can be done. In the broadcast world it's accomplished through the measurement of "Return Loss". By measuring the system return loss at the line input (generator end) and deducting twice the line attenuation, we get an indication of the load

return loss thesis value is easily converted to vswr.

Return Loss:
This is the dB value of absolute reflection coefficient.
It is rather curious concept of transmission engineering.
This loss value becomes 0 for 100% reflection and becomes infinite for
an ideal connection.

RL = 20log((VSWR+1) / (VSWR-1))

Voltage Standing Wave Ratio (VSWR):
This is the ratio of maximum voltage to minimum voltage
in standing wave pattern.
It varies from +1 to infinite.

VSWR = (1+(10^RL/20)) / ((10^RL/20)-1)

These are good and valid measurements which should be performed at
initial installation of the system and periodically verified throughout
the system life.

Return Loss/VSWR is only one of many measurements that should be
periodically done. DC measurements such as megger. LO-Ohms are also
very important.

Hi,

Simple question,

Is there somewhere on the Internet a website dedicated to the release of stories about DXpeditions (I think well to ARRL but their text is quite small), there are CQ and QST but its on paper and not dedicated, but rather a website covering most of these activities and in anotehr way that simply listing the date of their QRV (membres, qsl, date, story, rig, etc, etc) ?

Thanks in advance

Thierry

I'm tempted, but somehow your message gave me another idea. I think I'm going to take the PC to an entirely different location miles from here and see if get the same problem.

Ah, you know about us. I'm not a ham, but I will be speaking to our local club in January about radio astronomy. I used to have my hair cut by the former mayor. I'll have to ask my present barber if he frequents her shop. Maybe he attends the ham meetings. I only go to them when I want to promote RA, which has been 3 times. Although I went a few weeks ago to find out if anyone had a Icom R7000 rcvr. No luck. However, my opportunity to buy one disappeared within a few days of that meeting.

I may have one of those analyzers here somewhere. Lowe's is a long way from here, but we have one very good hardware store that would be a good candidate.

Probably nothing. However, I'd be willing to bet that I wouldn't have this
problem if I were 100 miles closer to the radio station. The Crane device
has been so ineffective its baffling as an issue aside from the one about my
radio. I built an FM signal booster when I was 14 that showed more promise.
Well, I've got 28 more days to return it. If it shows nothing more, I will
be out about $7.00 for return postage--rental fee?

After installing a 2 meter horz and a 6 meter horz beam, our mask was too short and the 2 meter beam was only 23" away from the 6 meter and the preformance for the 2 meter antenna sucked. I knew it should have been at least 40 " away. Now we are going to put up a cross boom, 10 feet across,and mount the antennas on each end, any thing to look for for other screwups?

JK> relates to relativity.

I think a saturable core can be used to measure a static magnetic
field. Early computer magnetic core memories worked like this.

Relativity transforms static fields into dynamic fields by adding a
velocity component to the measurement.

JK> Perhaps it's true that an electric field is simpler create than to

That Leyden Jar experiment was measuring charges not the E field
itself. An E field doesn't require the exchange of charges.
I wonder if it is possible to directly measure an E field by the
effect of the virtual quanta in its close vicinity?

Owen, it's pretty obvious that you were manufactured with a
lower tolerance (+/- 0.1%) than I was (+/- 20%). :-) Over on
QRZ.com, I suggested that the average amateur radio operator
has a hard time implementing a choke in a high-impedance
environment. W8JI said he could do it. I responded that, by
no stretch of the imagination, was he an "average amateur
radio operator". :-)

I was referring to the similarity to a rotating coil gaussmeter. I think what you're describing now is something more akin to the fluxgate magnetometer.

> Relativity transforms static fields into dynamic fields by adding a
> velocity component to the measurement.

I see. Is Omni magazine still in print by any chance?

> That Leyden Jar experiment was measuring charges not the E field
> itself.

Leyden jars store charge. As I said before, they produce an indication by relying on the electric field between charged surfaces and the resulting Coulomb force. The more charge stored in the jar, the greater the electric field. Charge, E field, and Coulomb force all being in proportion, the Leyden jar produces a response in proportion to all three.

One wavelength at a frequency of say 1070 kcs is a little less than 300 metres (approx 1000 feet?).
An antenna of either length will be very 'short' compared to the 'wavelengths' involved and will not be close to resonance.
e.g. For quarter wave resonance (approx 75 metres or about 250 feet; for 1070 kcs and nearly 400 feet for say 670 kcs) required.
Any 'too short' antenna will be will be badly mismatched (energy loss!) to the impedance of the co-ax.
This suggest that some kind of untuned impedance matching transformer, suitable for the frequencies in question, might be used to transfer as much energy as possible to the co-ax transmission line?
Seen this done with short 'whip' antenna operating at Broadcast Band/Medium Wave frequencies.
Transmission line should also be matched at the receiver end?
100 feet of coax at those frequencies should have low loss?

Absolutely. If the station signal is relatively stronger than the computer noise, the computer's RFI will not be so much an issue. Right now, they are about the same strength. Moving the computer will probably help a lot.

Just out of curiosity, what is the frequency of the station you are trying to recieve?

And while we are at it, is the noise on the radio in just one spot, or is it on pretty much the whole band?

I would like to relate my experience. As you
did, I carefully selected a new computer case
and power supply from the stock at <redacted>,
paying careful attention to the FCC logo on the
power supply. After moving the mother board
over and turning it on, it completely wiped
out reception of the local 5kW station on 550 kHz.
Fortunately, I had picked up a couple of surplus
Corcom line filters (Model # 10ESK7)at a local
hamfest three years earlier (it pays to collect
junk). I spliced it into the computer power
cord and it cured the problem completely.

I don't have any experience with the Radio
Shack line filter (Catalog # 15-1111), but it
looks like it might do the job for you.

3992. Mobile 2m/70cm antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2005-11-30 19:24:47 UTC
From: Rod Maupin <gridman@ywave.com>
Message-ID: <11orv408qms0pfd@corp.supernews.com>
Source record: 67239

I recently bought a Larsen 2m/70cm NMO mag-mount mobile antenna for my truck. It's the first time I've ever owned a mobile antenna because I don't do that much driving (I work from home). I don't have a mobile radio in the truck, I just have an HT.

What I wanted to do was hook up my Icom W32A to the mobile antenna when I'm in the truck. So, I put the mag-mount on the middle of the pickup roof and started driving. I compared the mobile Larsen antenna to my Diamond RH77CA HT antenna. What I noticed is that with the Diamond antenna on the HT inside the truck, it consistently pulls in more signal (on both bands) than the Larsen mobile outside the truck. The Diamond antenna is of course an HT antenna, so it's optimized for HT use.

Is this normal behavior for a mobile antenna hooked up to an HT? If it's not normal, then this is not that great of a mobile antenna.

I stuck the mag mount on the roof and ran the coax in through the sliding window on the back of the cab, so as not to pinch the cable. I had to use a UHF to BNC adapter to hook the cable to the HT.

I just checked and I don't see any pinched places in the coax.

Perhaps...

Now, I think you have told us over several articles that you are using an SGC500 into a 30 ohm load on 7.15MHz. That 30 ohm load is a result of feeding a dipole with 90' of ladderline, which I estimate has 0.9dB of loss under those circumstances.

If your transmitter was delivering 500W to the feedline, about 100W is lost in the feeder.

Do you know how much power your amplifier delivers to the feedline? It is likely that with a load VSWR of 1.7 it may have reduced output, it is also possible that it is delivering even more than 500W to the low Z load.

Yes, there is a measurable force. The Casimir Effect is the action
virtual particles have on a pair of parallel metal plates, pushing
them together (only by an extremely tiny amount). This is because more
virtual particles are created outside the plates than between them.

No,not the small beams. I'm mostly worried about the 2 large HF
antennas. The loop
for 80m encircles one leg of the linear-loaded dipole. I was under
the impression that
the "inside" of a loop on HF is the most important factor. I.E., a
circle is THE best loop!
The most area 'inside" makes for the best trans. and recieve.
No, I never use both at the same time. On
recieve,maybe. Do you think that
the SWR's would be different IF they weren't near each other!

Thanks for the interest !

Now please be a gentleman and please don't go putting words in my mouth.
Here a quote of my exact words:

"Speaking of indirect measurements - let's say the feedline Z0 is 380
ohms with a VF of 0.9 and a length of 90 ft. The measured resistance
at the current maximum point is 30 ohms on 7.15 MHz."

Clearly, "let's say", is a hypothetical postulate. I freely admit that
I pulled those values out of thin air. Going back to my web page reveals
that the feedpoint impedance on 40m for my 130 ft. dipole was really 38
ohms. Nonetheless, I can still make my point assuming the 30 ohm value
which would have been perfectly acceptable to me.

> If your transmitter was delivering 500W to the feedline, about 100W is
> lost in the feeder.

With a 1.7:1 SWR???? Maybe you should reprogram your calculator to take
the square root???? The ratio of Pref/Pfor for an SWR of 1.7:1 is 0.067.
Methinks you might be using the voltage reflection coefficient?

500(0.067) is 34 watts, not 100 watts. The SGC-500 laughes at 34 watts
reflected. (I swear that is true. I have heard it laughing to itself in
the wee hours during a contest.) Seriously, that amp is not known as
"The Brick" just because it looks like a brick.

> Do you know how much power your amplifier delivers to the feedline? It
> is likely that with a load VSWR of 1.7 it may have reduced output, it
> is also possible that it is delivering even more than 500W to the low
> Z load.

An SWR of 1.7:1 is nothing to worry about unless you think the percentage
power reflected is the same as the percentage voltage reflected. Don't feel
bad, many others have made that same mistake. Most people are programmed not
to think within a power/energy context and it gets them into trouble with
such concepts as "reflected power just sloshes around from side-to-side" and
"gobbledegook" applied to any attempt to track energy in a transmision line.

The SGC-500 is speced to tolerate an SWR of 6:1. That means that it can
dissipate more than half of its output power and keep on ticking. I
don't recommend allowing that to happen but that spec is why I don't worry
at all about reflected power unless the SWR is in excess of 2:1.

If we keep arguing, one of us is bound to make a mistake that the other catches. I would guess that your above mistake bothers you a lot more than it bothers me. :-)

Get your innovation noticed. The Wireless Innovation Network of BC (WINBC), along with its key sponsors Lucent, Nokia and TELUS Mobility is now accepting entries for the Wireless Innovation Contest 2006 (WIC'06).

WIC'06 is looking for looking for wireless success stories and solutions that are tearing down barriers and showing the most promise for rapid market adoption.

With an estimated benefit valued at $100,000, WIC'06 winners are rewarded with targeted exposure in media and at trade shows, inclusion in a special case study publication, and a one-hour mentor session with the panel of judges during CTIA Wireless.

Find out more today by visiting www.winbc.org/contest.

Lets leave that issue alone.

>
>If we keep arguing, one of us is bound to make a mistake that the other
>catches. I would guess that your above mistake bothers you a lot more
>than it bothers me. :-)

Well, I think we are agreed that you made a mistake in identifying a
mistake, if I am not mistaken!

No, back on track, I thought you might have measured forward and
reflected power at the amplifier output on the 30 ohm load, to deduce
the net forward power, then by allowing for the line loss, you would
have the net power at the feedpoint (most of which will be radiated in
some direction or another).

One could then calculate the performance of the feed configuration
compared to what would be delivered to an ideal nominal load with no
feed loss.

The whole excercise goes nowhere, because it seems that the 30 ohms
scenario is "hypothetical".

Your original mistake was in making a posting that caused me to
misunderstand. :-) Your loss calculator gives 0.762 dB loss for
90 feet of Wireman #445 with an SWR of 12.7:1 on 7.15 MHz.

> The whole excercise goes nowhere, because it seems that the 30 ohms
> scenario is "hypothetical".

I knew it was thirty-something ohms so I said "30". It was
actually 38 ohms indicating an SWR at the source of 1.3:1.
That's acceptable losses for me. If I used an antenna tuner
to achieve a 1:1 match, it would probably be a wash.

Which is probably a good question. At what SWR should one
install an antenna tuner? My IC-706 seems perfectly
happy at 2:1.

810 AM, KGO. Good question about the width of noise. Let me check ...

I just took the radio out near the PC, and operated it on battery.

With the PC on, and moving in steps of 10KH from 700 to 900:
noise almost everywhere execpt at 830, which is about 3 miles from my house
and over a hill.

With the PC off, some noise everywhere, but 710 (station and somewhat
noisyg), 740 (station and somewhat noisy but not bad-- KCBS inSF, CA), 810
(clean), 840 (station and somewhat noisy). In other words things improved
quite a bit.

The RShk ferrite rectangles didn't help. Interesting about the Corcom
filters. I'm going down to a radio shop on Friday, HSC in Sacramento. Maybe
I can find something there.

I just checked Google with "Corcom line filters Model # 10ESK7" and found
some hits. Look like maybe they are $5.00.

Interesting finding about the width of the noise on a msg I just posted a
few minutes ago.

>
No, the staples shouldn't hurt.

> b. Does the roof degrade performance ? How about when wet ?
>
A wet roof is somewhat lossy, so it certainly won't help.
But an attic antenna can still work for you, as it has for others.

> c. Would you expect considerably better performance if this exact
> same configuration was outdoors, at the same height ?
>
Yes, outdoors should be somewhat better. It might also allow a
better configuration.

> d. Would it be better if it were soldered back at the beginning, thus
> making a true horiz loop (with about a 10 foot vertical run to the
> receiver? Why ?
>
If you're talking about creating a circular monopole, no that would
not be a good idea. It would probably have much the same effect
as cutting off the far half of your wire.

> And I guess i should ask: For a single straight random length wire,
> is the most sensitivity perpendicular to the wire direction ?
> (assuming20 feet off theground, and perhaps 60 feet in length)
>
It's more complicated than that, and depends on frequency.
Don't worry about directionality unless you plan to build a
sophisticated directional antenna.

> Would you expect this to be much better than the indoor configuration
> I now have ? Why ?
>
It's not clear what "this" refers to.

> Is there a good pix on the web showing the lobes for this configuration;

> harness like I would normally do on a single antenna?

This doesn't match what you are speaking of in questions 1 and 2. You
cannot have the gain you desire and have the second set of antennas
differently polarized. That is a different configuration which requires
a feed that gives you circular polarization.

Now, you're trying to trick me... did you mean Wireman 554?

It does show 0.76dB for 90' of 554 with a 30+j0 input Z at 7.15MHz.

The 0.9dB stated earlier was (as stated) for 552 which had a Zo closer
to your 380 ohms, whereas 554 is 360 ohms.

>install an antenna tuner? My IC-706 seems perfectly
>happy at 2:1.

Given that some radios (including the IC706-IIG) reduce drive power at
high VSWR as a protection mechanism, you may want to install an ATU to
develop full power output. My recollection is that the power output of
the IC706-IIG is significantly down at VSWR=2, but it probably also
depends on the actual load impedance.

A likely scenario could be that the radio only develops 50W of output,
and only 40W makes it to the feedpoint (assuming 1dB feed loss). The
ATU might raise that to 100W of output, less tuner loss and feed loss
giving 75 to 80W at the feedpoint. Mere fraction of an S point... but
if you have a 100W transmitter, might as well use it, and besides, the
technical challenge of achieving that goal and measuring the
achievement might be part of what amateur radio is about.

Take a look at the 15-1111 on www.radioshack.com.
It is NOT a clamp-on ferrite choke, but rather
a filter like the Corcom. I just thought it might
be a bit more accessible. But if you can find a
10-amp Corcom, go for it! (Actually, a 3-amp model
should work). Anyway, your problem is definitely
solvable, and for relatively little $$$.

All,

I have been trying to determine the operation of a loaded vertical on 75 meters and over a less then perfect ground. It is inconvenient to measure and change do its location.

After many attempts to solve this I have struck upon a solution to 'get close'. I have decided to build a model that works on 2 meters. This will be small enough to construct in the shack and to experiment with various 'grounds'.

What are the pit falls in doing this?

Thanks Dan kb0qil

Hi Dan,

One will be in the size of the components. If you use, say, 1/4 inch
tubing, then are you prepared to erect the full-scale with 10 inch
equivalents? Same goes for that coil load which is going to suffer
enormously with skin effect at 2M - unless you are going to build a
large coil at 75M.

Ground characteristics are not the same for 75M as they are at 2M.

Umm, let's see, the radiator and radials, the loading coil, ground -
have we left anything out?

I fully agree the transmitter load is what the transmitter sees.

But his meter does not measure it.

His meter simply tells him whether or not its resistance is 50 ohms.

Which is all he wants to know anyway.

Source record: 67272

To make an exact scale model of an antenna, you not only have to scale all physical dimensions, but also the conductivity - the model's conductivity has to be freal/fmodel times the real conductivity. (Dielectric constant and permeability remain the same in the model as in the real antenna.) So in order to test the efficiency of various ground systems, you'll have to bury radial wires in model "dirt" which is several times more conductive than real dirt, while having the same dielectric constant as real dirt. (For example, if the real antenna is for 7 MHz, the model "dirt" will have to be about 20 times as conductive as real dirt but with the same dielectric constant.) Technically, you also have to do the same with the antenna conductor, but hopefully the conductor loss will be small enough that you won't have to worry about it. If the loading coil loss is significant, you'll have to construct a model coil with a scaled inductance but the same resistance (that is, the same Q) as the real one.

The pattern of a vertical antenna is heavily influenced by the conductivity of the ground extending several wavelengths from the antenna. So if you want to realistically evaluate the pattern, you'll need to extend your highly conductive model "dirt" to at least that distance.

Then there's the problem of measurement. Nearly everyone seriously overestimates his ability to accurately measure RF quantities such as impedance and field strength at HF. It's even more difficult at 2 meters. If you even want to attempt this, you should begin with models of several antennas of known characteristics, such as a quarter wavelength vertical and a resonant near-quarter wave vertical. See how closely your measurements agree with theoretical results. If and when you can get close agreement, then you have some chance on trusting measurements of other antennas. But even then it's not a certainty.

Those are some of the pitfalls.

Interesting thought but impractical. It could be the installation (e.g., grounding) vs. the supply itself. Event if the PSU itself, proving it would be a chore.

I have never witnessed my IC-706 folding back at any resistive
load between 25 ohms and 100 ohms. My IC-706 manual says, "When
the SWR is *higher* than approx. 2.0:1, the transceiver's power
drops to protect the final transistors."

Roy,

Thank you. My first objective is hopefully relatively simple. I would like to determine resonance and measure Z. In order to do that I will use an HP 8405A and directional couplers. Your suggestion is to practice that on known antennas. That makes sense. Given that I have relatively good generators and can measure forward and reflected signals at the antenna, is that sufficient to measure model impedance?

Dan

Thank you. I am not planning to scale the model, rather I am planning to learn how to measure. My first goal is to build an antenna with a relatively low radiation resistance and measure it.

Where can I learn about the difference in ground characteristics between 75m and 2m? William Orr wrote that a cross mesh under an HF vertical approximated a perfect ground. It should be relatively easy to do the same under a 2m model. I assume that metal reference ground would react the same.

Thanks - Dan

That's only where the mesh is installed. Ground
reflections and attenuation extend beyond the
mesh area. How high above the mesh are you going
to position the 2m antenna?

I've put up complete antenna systems that seem to approximate a perfect
ground .. some of them commercial products :)

4036. Ground-Level HF Beam Tuning?

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-01 16:23:30 UTC
From: Brian Kelly <kelly@dvol.com>
Message-ID: <1133454210.047291.209170@g44g2000cwa.googlegroups.com>
Source record: 67083

I'm mulling the design/homebrewing of a hexagonal 20/17/15/12/10M wire beam a la the Traffie Hexbeam. The problem with just about all projects like this is the number of up/down iterations required to tweak the tuning of the things. Put it up, calculate the required changes in element lengths, take it down, make the adjustments, put it back up to check it again, pull it down and go thru the whole cycle ad nauseam. Pain in the tush.

I've seen suggestions here and there about simply aiming a beam vertically upward and doing all the tuning at ground level instead. Which would save an awful lot of time and effort. If it works. Does anybody around here have any experience with this method and if so how succesful was it?

Thanks,

Brian w3rv

Works fine with a yagi, I've always just lashed a 2 x 4 to the tower and "hung" the antenna off the side of the tower pointed straight up. There's a null off the bottom of the yagi, and it ignores the tower as well. Not sure of the topology of your "hexbeam" thingie, but if you can get it to ignore things around it, the reflector, if it's doing any reflecting at all, will remove the ground from the tuning process.

It will get you close. However it really depends on the front to
back of the antenna. Dipoles do poorly this way, 2 element beams
slightly better. I've done 3 element 6m beams with the reflector only
4ft off the ground pointing up with excellent success. Seems the
breakpoint is some where around better than 10or 12 DB F/B ratio.

You do need distance from the ground or it acts like a reflector
and messes with your measurments.

For 20m I am planning a quarter wavelength vertical radiator with 4
eighth wavelength radials, mounted 12 feet high.

1/8 wl radials, with an elevated ground plane won't work
worth a hoot. They won't be resonant.

If I add another 4 radials cut an eight wavelength for 30m, will it be
easier to operate on 30?

Not really, unless you have a way to tune the radiator.
All elevated radials should be 1/4 wave long, unless a
case of using longer, such as 3/4 wave. 1/8 radials are
ok ground mount, but not elevated. Elevated radials must
be tuned and resonant to really work.

Another local Ham and I have built two monoband 20 meter versions of the
HexBeam
utilizing info from W1GQLs hexbeam website (one with PVC spreaders and one
with fiberglass rod spreaders). Neither had to be adjusted at all after the
original wire length was cut. Mine has usable tuning at just above ground
level and it's expected to get only better with height, as the other one
did. Granted, we didn't have the other band elements to fuss with. If you
can get element lengths and vertical separation distances from someone with
a working multibander chances are you won't need to do any adjusting on
those, either. W1GQL has suggested, with the finite lifespan of such
antennas and the current lowpoint of the sunspot cycle, that there is no
overwhelming need for 10, 12, and 15 meter elements for at least the next
couple of years. You might try building your antenna as a monoband 20 meter,
but construct the antenna with sufficient spreader tension and bow depth
that you can later add additional bands. The foregoing advice is free and
not necessarily valuable, but is given with friendly intent.(G) My own
fiberglass HexBeam has a 30" bow depth and I may yet attempt to add a band
or two later. Good luck with yours however you choose to build it.

I'm wondering
if a short vertical with long elevated radials would result
in an "off-center-fed" vertical.

Not the way I see it, just as long as all the radials are
equal length. The reason I don't see it, is the radiation of the
radials should pretty much cancel if all are equal. Not
quite the same as the single radial in that situation.
If you had one radial, maybe so...

Hi Dan,

Reggie's method of measuring earth conductivity in a coaxial tube
would work in these very short wavelengths (at HF it would be a joke
due to the necessity to survey to many meters of depth beneath the
system and out beyond it).

Aside from that, you would have to scrounge the web for references;
and they are actually quite numerous, but exceedingly tedious to sift
through. Basically, perform a search on soil characteristics for
ground penetrating RADAR. There is a lot of work that starts in VHF.
From this you might anticipate most references are very military in
nature. The problem of the sift is that many of these studies are
vertical niche research and may discard the paths of your interest.

Another method would be to reverse engineer it and find the soil
characteristics by discovery. That is model your construction, and
measure it both and compare results. The difference would probably be
the soil characteristic if you pay close attention to the details of
modeling and construction both. [By modeling, I mean in software.]

> If you had one radial, maybe so...

I just ran one on EZNEC. The feedpoint is at 23 feet and there
are four 23 foot radials drooping at 45 degrees. (I already
had this one modeled.)

With a 23 foot vertical section, the feedpoint resistance is
56 ohms on 10.2 MHz. 234/10.2 = 23 feet

With a 12 foot vertical section, the feedpoint resistance is
84 ohms on 16.4 MHz. 234/16.4 = 14.2 feet, 2.2' longer than 12'.

It looks like (with slanted radials that radiate) there is an
"off-center-feed" effect, i.e. longer radials require a shortened
vertical section.

If you want to model 75m ground, you need to begin with what you assume the ground characteristics to be at 75m. Let's say you have average ground, with conductivity of 5 mS/m and dielectric constant of 13. For your model, you'll need something with conductivity of 5 * 146/3.8 ~ 192 mS/m conductivity and dielectric constant of 13. I have no idea where you might find such a material.

>William Orr wrote that a cross mesh under an HF vertical

No problem approximating a perfect ground. If you have a perfect ground under your 75 meter antenna, it won't be hard to make a decent model of the perfect ground. A piece of screen or hardware cloth would do fine. The trick will be making that perfect ground under your 75 meter antenna. And unless you do, the model won't behave the same as the real antenna.

Roy Lewallen wrote:
"You can find the explanation for why this is in any electromagnetic text."

I found it in Terman.

As we all know, we place correctly polarized dipoles, for example, parallel to the wavefront for maximum response. Terman confirms the electric field in this instance induces no energy in the antenna. It all comes from the magnetic field.

If antenna current flows, no matter where it comes from, loss resistance causes a voltge drop. That`s why the wire needs to be perfect. The electric field produces no voltage in the antenna because the wavefront has the same voltage across its entire surface. That`s because it all left the same point at the same time. So, a wire parallel to the front has no difference of potential induced by the wavefront`s electric field. It all must come from the mgnetic field.

On page 2 of his 1955 edition, Terman says:
"The strength of the wave measured in terms of microvolts per meter of stress in space is also exactly the same voltage that the MAGNETIC FLUX (my emphasis) of the wave induces in a conductor 1 m long when sweeping across this conductor with the velocity of light."

From the above, it is seen that the electric field is not effective in inducing current in a receiving antenna parallel to a wavefront. All the energy intercepted by the antenna is induced by the magnetic field.

Best regards, Richard Harrison, KB5WZI

For one, there is no such thing as a perfectly conducting antenna, except where one might truncate precision and measure at D.C. Even for a perfect conductor (absolutely no Ohmic loss), it still exhibits radiative loss, and any current through this loss must exhibit a voltage (the same one described by Terman). Perhaps you intended this, but you fail to offer Rr, a significant component.

>The electric field produces no voltage in the antenna because the wavefront
>has the same voltage across its entire surface. That`s because it all
>left the same point at the same time.

An electric Dipole exhibits a loci of points in space that has the same voltage, broadside to the radiator. And this loci is orthogonal. All paired points in 3-space (in the same polarization to the dipole) exhibit a potential difference. True, at a great distance it may be meager, but the common evidence of reception proves it is adequate for detection and measurement. Your discussion above is for the insignificance of phase difference at a distance.

>From the above, it is seen that the electric field is not effective in
>inducing current in a receiving antenna parallel to a wavefront. All the
>energy intercepted by the antenna is induced by the magnetic field.

From your copy of Bailey, review the text, and reconcile his remarks.

For others following the original poster's query for a source of discussion about the physics of reception:

I would suggest reading the chapter "The Theory of Signal Interception" (all may be advised this chapter runs to 63 pages), specifically the first two sections "How the Antenna Intercepts a Signal," and "The Current Treatment" from which I will lightly quote to amplify the comments above:

"This electrical resistance is not only due to electrical conductivity of the metal of which the rod is composed but also due to other factors.... the predominant resistance is, strangely enough, largely due to the fact that no electrons can move on the antenna surface without also sending radio energy back out into

space."

By the decimation of the problem of treating a large surface as many small ones (segmenting the antenna) Bailey offers:

"At each point along this rod we can arbitrarily say that a small but finite voltage acts."

Notice the "acts" which is an initiator or causative agent, not a passive result. This is not to say such action is in isolation, Bailey clearly observes that E/H are inseparable and he offers that the wave bootstraps the antenna's response (the point of his emphasis on immediacy from Roy's Chapter 4 quote).

It looks like time to remind readers that charge isn't the same as electrons. On a wire, charge moves at nearly the speed of light, while electrons only go a few miles per hour. Most of the relevant theory actually deals with the interaction of fields and charge, not fields and electrons.

Good point. Charge can be holes, or electrons, or even ions. It is the fields which move at the speed of light. Charge tends to have to hang around with the charge carriers. But once a field arrives someplace, it will immediately influence the motion of charges that happen to be hanging around there locally.

My ISP still provides usenet, but you can always go to google groups,
and read and post for free. There are other free news providers that
have web portals as well.

If you like using the old rn, nn, and tin servers, get a shell account
from Panix. You can telnet or ssh in from anywhere in the world, type
"rn" at the shell prompt and go. And it's ten bucks a month and the
tech support is better than you've ever had from Computer Services at KSU.

When I bought a similar antenna, a Larsen 2m/70cm mag mount (mine is
about 20 years old, but may be the same exact model as yours) anyhow,
I had to cut the vertical element with a file to get the SWR down,
using a Bird wattmeter. The antenna, as it came from the factory,
needed quite a bit of diddling before being resonant.

Have you checked SWR, and/or adjusted the vertical length?

I was terribly disappointed in the MFJ case and sold it on Ebay then bought
an aluminum case off Ebay that works perfectly and has room for several
adapters and a cable or two as well as the instruction manual for the 269.
It is a great instrument but I wish they would fix the UHF switching
problem. Looks like a latching relay would solve the problem real easy, go
figure. Anyway here is a URL to one of the auctions:
http://cgi.ebay.com/NEW-ALUMINUM-HARD-SIDE-PRO-DELUXE-DIGITAL-CAMERA-CASE_W0QQitemZ7568420
345QQcategoryZ50505QQrdZ1QQcmdZViewItem

I also bought a laptop case from the same company and both were outstanding
quality. Good heavy side walls and nice interiors. Take a good look at the
interior dividers on the above auction. The 269 fits exactly.
Good luck and 73,
Ken

What, have you been talking to the guys at HRO again at how people will come in and get technical advice for an hour and then go home and order on-line again or something? :-)

Seriously, your point is well taken, although I'd suggest that all the product reviews you get from, e.g., Amazon.Com can actually be more useful than the information you'd get from a salesperson. There's no inherent bias (to want to sell you something), and you get to see comments from people with a wide range of background. (It's always kinda amusing to see people trash, say, some classical technical book when the real problem is that they're just not well enough educated yet to appreciate what they're reading!)

I have a suspicion that, depending on whether you're pro- or anti-Wal*Mart, that number can easily more around by an order of magnitude...

Presumably that $1.5B translates into higher taxes, right? The average person would rather pay $1 at WallyWorld and $0.25 in taxes rather than $1.10 at a different store... it's just human nature. And even if you convince the average person that their taxes are higher due to WallyWorld being around, most of them would just say to cut tax rates and hence reduce spending on whatever their favorite 'target' is -- the military for more liberally minded individuals, social programs for conservatives, etc.

> When you look at if from the Chinese
> perspective, they are getting gang-banged too. The presentation
> showed how Wal*Mart paid workers 6¢ apiece for an item selling at $12.

That strikes me as a red herring. For many products, there's very little relationship between the selling price and any one constituent cost involved in producing it, such as labor. (How much were the labor costs of the salesguy who sold you a one karat diamond ring for, say, $10,000, after all?)

1) Many people like the sound of Bose. Regardless of how distorted that sound might be, the fact that people like it is most important. (And purposely distorting sound is very much the premise of many effects boxes used to produce music, after all!)
2) Bose does a good job of marketing their product as something that appeals to the 'hip' crowd, just like Apple has done with the iPod.

> Its all marketing BS like the Wizbang cables to hook things up.

Yep, but given that something like a stereo system is 100% a 'want' and not a 'need,' anything goes! I.e., no need for the government to regulate it, let people spend their excess cash on whatever they want...

That is outright false. Because I can very easily demonstrate
detecting a static E-field by waving a sensitive probe across it.
An antenna is just a stationary probe with a moving E-field. It is
equivalent. Terman sucks.

A*s*i*m*o*v

Yes, that is pretty steep. However, Kraus's 3rd edition of "Antennas" is
$165. I'll be down in the SF Bay Area this weekend. Maybe I can find it at a
library down there, or arrange to get an interlibrary loan. I use albris on
occasion. Glad you reminded me of it.

Interesting. It's in San Jose. I'll be there Saturday. I wonder where they
are? (Cheapestbooks). Interesting source.

When I was a student (a very long time ago), I would sometimes buy paperback
books of many texts from Blackwells in England. The price was usually about
1/2. Sometimes (back then, and maybe still), one could by tech books from
China that was on almost tissue paper pages. They were quite cheap.

The "thingie" is a 'po boy's horizontally collapsed vertically expanded
two element yagi sort of contraption.

http://midcoast.com/~w1gql/hex/hexbeam.htm

Great little rotatable array for those in situations where installation
space is cramped. Which is what I'm stuck with. Just like full-size
yagis they have decent F/B ratios, normally anywhere from 10 to 20dB.
So based on your experience I should be able to use the Sidearm Method
and get the results you've gotten.

Thanks!

. . . Good. Beats having to taking the beam down and putting it back up several times just to get in the ballpark. I expect to have to do a couple of these final tweaking cycles after rough tuning at ground level. Would be a *big* help.

Per my response to W4ZCV hexagonal beams typically have 10-20 dB F/B ratios so they're in range of your "breakpoint".

> You do need distance from the ground or it acts like a reflector
> and messes with your measurments.

Understood. Looks like you and W4ZCV are basically in agreement so I'll follow you two in this direction.

Thanks!

Without any noticeable resonant point or F/B ratio shifts??

I'm early into my education on building hexbeams and I've seen a bunch
of this type info published but have not yet dug very far ito it.

> W1GQL has suggested, with the finite lifespan of such
> antennas and the current lowpoint of the sunspot cycle, that there is no
> overwhelming need for 10, 12, and 15 meter elements for at least the next
> couple of years.

I don't particularly agree with that. This past weekend hi-band
conditions were below average for the current period but any number of
individual stations operating in the CQ DX CW contest logged hundreds
of 15M contacts each in dozens of countries. Their results on 10M were
dramatically down vs. their results on 15M but their results on 15M
were only down by maybe 20% compared with last year.

I've spent a lot of hours chasing DX on 15M thru a number of sunspot
lows. The biggest problem 15M has is that during the lows the
expectations are that the band is dead like 10M is dead and not worth
bothering with. So they don't. Which is their loss because any number
of times there are great openings on 15M but the few who do tune the
band are all listening instead of transmitting so of course the band
seems "dead". 15M is a gottahave here.

> You might try building your antenna as a monoband 20 meter,
> but construct the antenna with sufficient spreader tension and bow depth

> that you can later add additional bands.

That's reasonable. After thinking about it 12/10M really are coming up
as complete losses so a 20/17/15M version would be a good compromise as
far as the payoffs for the investments in effort go.

> The foregoing advice is free and

Here's another good book, "Optics", by Eugene Hecht, for $24, containing
the best treatment of superposition and interference that I have ever seen.

Asimov wrote:
"Terman sucks."

Termn`s writings have been exposed for anyone to criticize for most of a century. His 1955 edition has been out there for 50 years. No retractions or corrections are necessary.

Detection of static E-fields is not relevant.
Charles Coulomb in 1785 showed electric charges exert forces on each other that are inversely proportional to the square of the distance between them. This was the birth of the "inverse square law" as Coulomb`s discovery applies to magnetic attraction and repulsion, too.

In an electromagnetic field, propagation depends upon the electric field begetting a magnetic field and vice versa. On average, each field contains 50% of the total energy.

The electromagnetic field of an antenna could be calculated from the distribution of voltage on the conductors. Problem is voltmeter leads would be in the r-f field and this would tend to make measured voltages inaccurate. R-F current is conveniently and accurately measured with a thermocouple ammeter.

Strength of an electromagnetic wave is usually measured and quoted in terms of its electric field in volts per meter. This is the number of volts which would be induced in a one-meter length of wire placed in the field parallel to the electric lines of force. Volts in the wire are produced by movement of magnetic flux across the wire.

Best regards, Richard Harrison, KB5WZI

The yabut/gotcha is until the beam is acting like one you don't have
the F/B ratio to rely on so it may take an iteration or two before you

converge. Once you are in the fine tuning range it should work
well pointing it up. This is a problem that most Yagis don't have
as tuning is limited to tweeking the match for the driver and maybe
the driven element length to make the match work right. So what
regular yagis are tuned up pointing up they are really just having the
match set up correctly(usually).

And, using Google, you run the risk of being killfiled by a Great Many
usenet denizens because of the gawd-awful defaults Google uses for
follow-ups in its posting configuration. But, then, you knew that...

So, you being a *nix user, I can't see you getting excited about doing
usenet 'text work' with a bloated cartoon interface. I'm a *nix user,
too, and I can recommend Individual.net (http://news.individual.net/).
It's is the follow-on/re-incarnation of the free news.cis.dfn.de. It
costs 10 Euro per year and it's well worth it. I used the online sign-up
and paid via the FirstgGate (http://firstgate.com/EU/en/info.html)
service they use.

Now, if only slrn could score on top-posters. sigh...

Hi,

It seems that my location boasts 60 to 110 mph winds on a regular basis. I had put up a 1/4 wavelength 20m vertical with 1/8 wavelength radials elevated at 7 feet, with rope guys... and the wind blew it apart like so much tin foil!

Does anyone know of a decent commercial design for less than $1000 for a free standing 30 to 40 foot support that can take this darn wind???

Thanks,

The Eternal Squire

It begs the question, what was it made of? It must have been very thin metal
to blow apart only 16 feet, guyed by ropes.

Please enlighten us.

Ground system:

5 foot of 1 inch diameter galvanized iron pipe, halfway stuck in ground
with concrete.
1 inch diameter galvanized coupler
5 foot of 1 inch diameter galvanized pipe
1 inch to 3/4 inch copper reducer
1 foot of 3/4 inch copper pipe
4 tees: 3/4 inch thru vs 1/2 inch out, soldered lengthwise along
copper pipe.
an 8 foot length of 1/2 inch copper pipe soldered into each tee
tees are reinforced above and below radials with a hose clamp
coax shield connected to top of copper pipe

Radiator:
10 feet of 3/4 inch diameter copper pipe
9 foot carbon fiber fishing rod, handle epoxied and inserted into pipe
a wire is attached to copper pipe and run up to end of rod.
Hot end of coax connected to bottom of copper pipe

Ground system and Radiator are connected in-line with a PVC twist shaft
coupler designed for 3/4 inch pipe, weather sealed with epoxy. A gap
of 1 inch between pipes inside the coupler is filled with styrofoam to
prevent contact.

Rope guys are econnected to the top part of the shaft coupler, as the
middle of the shaft coupler is predicted to be weakest point.

Sure enough, a continuous wind in excess of 60 mph vibrated the shaft
coupler into 2 pieces despite the guys, the radiator then collided with
a radial, knocking a radial out of alignment and ripping apart a hose
clamp. I suspect the wind is going to finish the job overnight.

Sigh,

The Eternal Squire

4091. how to model frequency response of a loaded vertical ?

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-03 04:44:32 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <cOedndIan_EpvwzenZ2dnUVZ_sadnZ2d@comcast.com>
Source record: 67138

All,

I am creating a 'scaled' model of a loaded vertical. The model is complete and in place. However I immediately realized I had no idea of the 'theoretical' response. How can I calculate the expected impedance response of a loaded vertical? It a mid load construction,

the base in #10 solid copper 4 inchs,
the coil is .6 pitch, 1 inch diameter, 5 turns #12, measuring .72 uH,
and the top is 4 inch #12.

The antenna appears to resonate at about 112 MHz.

The instrumentation, a directional coupler measuring reflection is located at the base, directly under the 'ground plane'. This allows measuring input and reflected signal strength.

The question is: How can I plot the expected impedance from say 100 MHz to 130 MHz?

Thanks - Dan

I regret having written that Terman sucks. However, I'm reminded that
there is a lot of stuff missing in the 1955 edition of Encyclopedia
Britanica up in the attic. Clearly I don't say the EB sucks either,
so a 1955 book on electromagentic wave theory might be missing a few
things as well. Unless you believe everything that there ever is to
learn about EM is that 1955 book. But it is wrong to state that the
magnetic field alone is responsible for the interception of wave
energy in a metallic conductor.

Does anyone know of a good design for a reasonably high gain bidirectional antenna for a 440mhz video TX? I am putting a 4 watt A/V TX in an RC plane that will fly on auto pilot directly away from the RX, make a 180 degree turn and fly directly back. So to get the best range I was thinking some kind of bidirectional yagi. Depending on element spacing and how big of a plane I get, I can probably only have 3 elements maybe 5.

Same kind of location here, wide open to the Irish Sea.... but that wasn't a big antenna, and with the guys it certainly should have stayed up.

You're missing something here. Typical ham antenna structures are a mixture of over-design and weak spots, so maybe you should look at the wreckage in more detail and try to learn something from it.

OK, I just read your second posting and pulled this back from the outbox. From the top downwards...

* Fishing rod good. Carbon fibre not good (possibility of losses and detuning compared with plain fibreglass; definite loss of money compared with plain fg).

* Copper pipe not good in these long lengths. Ask yourself why everyone else uses aluminium.

* PVC pipe coupler not good... well, that you know.

* Again, copper pipes not good for radials. Copper pipe tees not good for supports. If the top part hadn't fallen down, those pipe tees would probably have been next to go.

* 3/4-in copper for your main support mast is a big mistake. The heavy radials flopping up and down create a huge leverage at this point, so that copper will be rapidly work-hardening and well on its way to breaking (may well have done so by your morning).

* In your wind conditions, 1-in galvanized pipe is way too small for the lower part of your mast. The only thing that kept it from snapping is that something else broke first.

* Were your guys helping to reduce the bending forces at the point where the coupling snapped... or helping to concentrate them? In your particular case, I'd bet the latter.

The big lesson is that the construction of a copper J-pole for 2m will not scale up to 20m wavelengths... basically because copper tubing is a

poor structural material, and as the model-makers say, "You can't scale Nature." When you increase the scale by 10x, you have to use different structural materials and techniques.

Again, ask yourself why everyone else uses larger tubing for masts; uses aluminium, not copper; and doesn't use small, soft plastic plumbing fittings. Have a look at HF antenna construction in the antenna handbooks and catalogues, and do what they do... because there's a reason for it.

>Does anyone know of a decent commercial design for less than $1000 for

Hang on now - that would be spending money to *avoid* learning something.

>a free standing 30 to 40 foot support that can take this darn wind???
>
One option that's surviving very strong winds here is a tapering fibreglass pole. I'm using a Spiderbeam telescopic pole that is almost 40ft high and strongly made:
www.spiderbeam.net/english/pole.php

The pole is tied to a very solid clothes-line post at about 7ft, and also guyed at about the 30ft level to prevent the worst of the swaying. In very strong winds it bends into an alarming S-shape, but by the nature of fibreglass it also springs back again.

Maybe I did not explain my question well. Considering only the VHF
antennas, I want to couple separately the vertical dipoles and the
horizontal ones. Then I could have two separate antenna feeds, one for
the vertical and the other for the horizontal plane. More pratically I
could use a coaxial relay to be able to switch between vertical and
horizontal.
The question is: can a system like that still be somehow used to have
RHCP and LHCP? Do I simply have to couple the two feeds like I normally
do with single antenna?

Thanks

I had put up a 1/4 wavelength 20m vertical with 1/8 wavelength
radials elevated at 7 feet, with rope guys... and the wind blew it
apart like so much tin foil!

It decided to blow it down so you could rebuild it with the proper
length radials...:(1/8 radials won't work too well. Why would you
use those? They are fairly useless on an elevated ground plane.
The decoupling of the feedline will be poor, and probably lots
of rf in the shack. Needs 1/4 wave radials to work correctly.
As far as the wind, you need to build a little stouter... Normally, a
short 16 ft radiator should be easy to keep up, even with 60 mph
winds. Shouldn't fall down if it was guyed. My 40 m ground plane
was 32 ft tall, mounted at 36 ft. Nearly 70 ft tall at the top. Only
my mast was guyed. No guys were used on the radiator. I used
a telescoping metal mast which shrunk down to a very thin size
as it neared the top. Was quite flexible. In heavy storms, it would
nearly blow sideways, but it never hurt it, and it always popped
back up straight after the wind left. That particular antenna cost
nothing..Made from an old butchered up 5/8 wave CB antenna as
the base radiator, and then extended with extra tubing.
Was looking at your 2nd post, and notice the details. Not
exactly the recipe for a solid antenna...You would be better off
using an old butchered CB antenna, etc. The cushcraft AR-10
makes a good platform for verticals also. It's a 16-18 ft 1/2 wave
antenna for 10m. If you use only the radiator, and redesign the
feed, thats a decent quicky 20m 1/4 wave vertical. The old heavy duty
5/8 CB antennas are good to use also. They have heavy duty
bases that are often reinforced. Thats what I use for my tall 40m
antenna, and never had a problem, but I did strengthen by adding
extra tubing , inside the tubing. IE: double wall... Copper is pretty
soft, and shouldn't be used for anything that needs real strength.

I use 2x(2"x4"s) fastened together for a 4"x4" support and 1/4WL
wire radials as ground-plane/guy-wires. The vertical section is
assembled from 6' telescoping aluminum sections following the beam
element design guidelines in the ARRL Antenna Book. The top 8.5'
is a stainless steel CB whip. It has withstood wind gusts of about
100 mph. As others have said, copper is a poor choice for a 20m
vertical.

A simple dipole will do what you want. That is a lot of power in the
airborne TX. 400 mw is still over kill and 40 mw will probably do the
job. At some point you will need to regain control with conventional
RC equipment and getting a signal into the airplane with that much
radiated power may not be easy.

If you are short on the RC airplane experience I suggest you consider
a Telemaster from Hobby Lobby. Smaller versions are available for
experience and the Senior (8 foot span) with carry many pounds of pay
load.

What you are considering is called an RPV and is a hot item in
military use now days.

Actually, pure aluminium is even softer and far more ductile than
copper and is useless as a construction material.

But some grades of copper/aluminium alloy, known in the UK as
Duraluminum or just Dural, have properties approaching carbon steel
and are corrosion resistant. Light in weight. Easily machined and
extruded. Maintain a good appearance. High electrical conductivity.
More expensive than steel.

They are used, for example, for ladders and scaffold poles. When used
for tubular rigid dipoles and antenna masts they collapse under high
winds only because the wall thickness is too thin. Commonly used for
radio chassis and sheet metal roofs.

But NOT pure aluminium, just a few percent of copper.

Reg.

Hello guys,

I recently picked up an old vector network analyser in working order
but minus the 3 interconnects between it and the
transmission/reflection bridge. These are specified in the manual to
be exactly 24" long, 50 ohms and terminated by N-type plugs.
I've been told the length of these patch leads is quite critical to
getting accurate measurements with this VNA, but am at a loss to work
out why 24" is specified when the frequency range of this device is
4Mhz to 1300Mhz. If it were only capable of measuring at one fixed
frequency, I could understand the need for a specifically cut length
of some fraction of a wavelength.
Can anyone explain the relevance of 24" in this context?
Also, will *any* 50 ohm coax suffice for this purpose or has it got to
be something special?
Thanks,
P.

Hello guys,

I recently picked up an old vector network analyser in working order
but minus the 3 interconnects between it and the
transmission/reflection bridge. These are specified in the manual to
be exactly 24" long, 50 ohms and terminated by N-type plugs.
I've been told the length of these patch leads is quite critical to
getting accurate measurements with this VNA, but am at a loss to work
out why 24" is specified when the frequency range of this device is
4Mhz to 1300Mhz. If it were only capable of measuring at one fixed
frequency, I could understand the need for a specifically cut length
of some fraction of a wavelength.
Can anyone explain the relevance of 24" in this context?
Also, will *any* 50 ohm coax suffice for this purpose or has it got to
be something special?
Thanks,
P.

I guess you didn't notice the part about an autopilot, I plan on having the plane fly out about 10 or 15 miles out and then back, not just where I can see it. I have several years and a few hundred hours experience flying RC planes but still plan on using a plane that is reasonably easy to fly so the autopilot has an easier time controlling it. I have a few tests I plan to do to check if the video TX will cause a problem with the RC RX. I will rig up a servo to turn the video TX on and off and will set a fail safe so that if the RC RX can't get it's signal it will shut off the video TX. I will first set the video TX to very low power (the TX I am looking at is adjustable from 0 to 4+ watts), then I will make sure my video shut off switch is working good then make small increases in the video TX power and see how far away I can fly the plane before the fail safe shuts down the video TX.

If the high power video TX does prevent me from retaking control of the plane from the autopilot/GPS navigation system, I have a plan B that I am working on. A system that will make adjustments in video TX output power at various way points, so it adjusts the power up as it gets farther away, and back down as it gets closer, this will have the added benefit of increasing the life of my video TX battery. I'm not sure how I will do that yet but I have a few ideas I am looking into.

The pipe thread area is a point of weakness and the overlap is way to short
to provide any strength. A better alternative is aluminum tubing with .058
wall thickness.

This allows decending sizes to fit with in one another. For example a 1"
6061 T6 10 foot long has an inside diameter of .884 and a 10 foot section of
7/8" (.875) will slide right into it. This would allow an overlap of almost
4 feet providing all the strength you need.

Good luck on your next installation.

it is likely the 'real' requirement is that they be exactly the same length.
though there may be some maximum length because of attenuation at the top
end. there is also a possibility that they figure in some length of coax
and calibrate that into the system, though i would think that is less
likely.

(This doesn't solve your problem, but might give you some info as to
why the reception of WIBC is somewhat difficult.)

Given your distances, then you are somewhere between Indy and Chicago.

WIBC drops their power significantly at night, and also the antenna
pattern shows that the available signal is probably the worst possible
given the antenna :-(. Here is a picture of the WIBC pattern, and
consider the WIBC towers are on the NW side of Indy.

Roy,

Thanks, I was able to enter the data into eznec and run the simulation. The output was 'confusing'. Eznec predicted 100 Ohm over various grounds. Other models predict 5 Ohms for the antenna plus ground resistance with a total of 10 Ohms or so. Which is correct? How can the differences be reconciled?

Thanks again - Dan

The phase shift due to the 24 inch coax cables are factored into the Network Analyzer for all frequencies and so any different lengths will cause the correction factor which is built into the analyzer to be wrong and that will make the reading displayed on the screen to be in error.

The phase velocity for most coax cables are similar, so I'd use RG-8 since that accepts type N connectors reasonably well. The impedance bump caused by a thinner cable being adapted to type N cables would be noticeable especially at higher frequencies.

The only major question is whether the original cables had a different velocity factor, and that I can't answer so I'd use the RG-8 and it should be close enough.

Is the Zo of RG8 52 ohms?

Is the instrument 50 ohms?

Would RG8 introduce error?

Maybe a mention of the model number would be helpful. My best guess
is that the absolute length is not very important as long as all three
are the same length.

The stability of the cable is likely more important than the exact
type.

Thanks Wes (and others - I'm building up a picture of what's what from
your contributions...)

The VNA in question is an HP 8754A made in about 1979.

>My best guess
>is that the absolute length is not very important as long as all three

Yup. So I've been given to understand. But is the loss factor relevant
over just 2 feet at 1300Mhz?
BTW, the guy that asked about the impedance of RG8: it *is* 50 ohms as
far as I can ascertain and if it *were* 52, it surely *would* screw up
the measurement, IMHE!

Try these guys http://www.valcom.ca/welcome.html they make antennas for coastal coast guard shore stations and military ship antennas I had one of the 74 foot shore/vessal antennas it was a 74 feet high with a capasative cap and worked like a hot dam. Mind you I got mine free for the taking at a Canadian Coast Guard station that had replaced the antennas with something bigger.
The Valcombs are used on board ships all over the world and on shore, I got mine where the wind was blowing on average about the same as what you have 90% of the time, a typical shore station locations.
The one I had up weighed 700 lbs and required approx. 6 yard of cement and it never even as much as moved when the wind blew. Sold mine to an amateur in SD aka tornado alley and last I heard he lost his barn but the antenna surived without even as much as a scratch.
Oh by the way it has a really low angle of radiation and worked fantastic for DX, best antenna I've ever used, next to a rombic on the Artic Circle, aka DEW LINE.

All,

Thanks so much for getting back on this... I am located about 50 miles west of Gallup, NM.
I am in a trailer park so I do not have a very large lot. Also while my super is a nice person, amything large enough to seriously ding a trailer if it fell would not be not okay with him. My wife also wants to put a storage shed next to the trailer fairly well adjacent to where I mounted my first pipe into concrete. That limits my choices further.

My YF is generous enough to allow me to keep trying with this antenna, but she is already concerned that I put $300 into it ($175 parts and concrete, $50 tools, $75 to hire someone who speaks propane torch) and thinks that I should leave the design and installation to a professional, hence my question about decent mounting for less than $1000.

For purposes of discussion the dimension limits to be about 25 to 35 foot vertical, and about 8 foot radius for mounted radials. I am allowed to create ground counterpoises up to 40 feet long as long as they snake into the back lot. Severe sway is not allowed as it could spank the trailer.

One thing I have noticed is that street lamps and telephone poles are unguyed but have no problem with this wind. Unfortunately, I am not close enough to either of them to use them for a mounting.

(I cannot move, I am committed to staying. I got laid off by my company in mid-september and we moved to a place where my wife could use her new master's degree in education... and we have to stay in this trailer right next to her school as a condition of her employment... it is, fortunately, low rent forced housing).

Questions:

1) Since I have an 8 foot limit for radials, could I have 1/4 wavelength helical radials for 40m that could fit into an 8 foot length?

1a) Could I do the same helical trick for the radiator as well?

2) My base 1 inch diameter galvanized pipe is presently 2 1/2 foot into a 2 1/2 foot cube concrete filled hole with 2 1/2 foot exposed. What could I screw in it that would not need guying, and would not bend nor sway in 100 mph wind, and how high could I make that?

3) If I run up a metal pipe to 20 foot and then an insulated wire from the dirt to the top alongside the pipe as my radiator, what effect will the pipe have on the radiating wire?

Thanks again,

The Eternal Squire

4124. how to measure antenna impedance ?

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-04 01:33:18 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <T72dnXshlbv82g_eRVn-ow@comcast.com>
Source record: 67171

All,

I am trying to measure antenna impedance. For this I intend to us a directional coupler to isolate reflected signal. After using the coupler for a while I believe that it introduces a phase shift, that shift seems to be related to frequency. This creates a bit of a catch 22. Antenna resonance is defined as the frequency where there is no reflected complex component. If the tool to measure this is also frequency dependent how can this be accomplished? Is this even the best method?

Do bi-directional couplers automatically compensate for frequency shift?

Thanks - Dan kb0qil

Hi Dan

Normally you would calibrate your test gear against a known resistive load first. If you coupler creates a phase shift that can be compensated for either in the test equipment or by varying the feedline length. (ouch!) All the network analysers I have used allow you to calibrate 50r, open or short.

You can further test you setup by measuring known lengths of coax "stubs" that would present a reactive load.

I imagine a directional coupler would introduce a phase shift as it has an electrical length that must be allowed for.

I saw a real impressive antenna impedence measuring device that used coaxial cable as the tuned reference elements. It was of course frequency dependent. It was made for 2M but I guess the design would be easy to replicate for other frequencies given. It has about 10% usable bandwidth. I was going to make one for HF with BNC terminated coax lengths for each band, but never did!

What you are measuring with a directional coupler is the complex reflection coeficiant. If the measurement is for low frequencies (i.e. < 30 MHz), and the load is at the input of the directional coupler, then you will probably obtain a realistic figure for complex "Gamma". Ideally you need a short circuit, open circuit, and 50 ohm load to determine if the system is calibrated.

Short circuit Gamma = 1 <180
Open circuit Gamma = 1< 0
50 Ohm Gamma = 0

If the load is at the end of a length of coaxial cable you have to comphensate for the phase shift error at every measurement frequency.

Since you are dealing with complex numbers it is tedious to determine the actual load impedance. The following app. note should help:

http://www.maxim-ic.com/appnotes.cfm/appnote_number/742

HP's app. note at http://www.sss-mag.com/pdf/hpan95-1.pdf is also very helpful.

Regards,

Frank

The noise from PC Power Supplies is usually radiated from the power cord and the house wiring. The
cause is often that the manufacturers cut cost by leaving out the L and C components of the line
filter. Usually you will find the place on the PSU circuit board to mount a bi-filar choke and two
or three capacitors. The capacitors are missing and the pads for the choke are jumpered. If you
can find an older junk PSU which has the components, just unsolder them from the junk board and
install them in your PSU. Sometimes the PSU's in Monitors have the filter components.

When I installed the filter in my old Pentium, the switch mode hash on broadcast band stations went
down by 30 db. Installing line filters outside the CPU Case had very little effect.

Network analyzers incorporate a concept called a "reference plane". This is a theoretical point at which the measurement is actually made. It's desirable to have this point be at the DUT connector. (In precision and/or extremely high frequency measurements, the point within the connector becomes important, and even a sex-change adapter can't be tolerated between calibration and measurement.) Software in the network analyzer is told where the reference plane is to be by means of a rather involved calibration procedure, then the network's software corrects for the phase shift and impedance magnitude transformation of the cable between the reference plane and the analyzer itself. It effectively makes the reference plane the point being measured, rather than the analyzer input terminal.

When you make manual measurements, you have to do the correction yourself. So what you need to know is the impedance and length of the line between your point of measurement and the DUT. This can be determined in the same way as it's done for some network analyzer calibrations -- by measuring the impedance with the DUT replaced with a short circuit, an open circuit, and a known load impedance, then solving the resulting set of simultaneous equations. Once you know the impedance and length of the cable between where your measurement is correct and the DUT, you can calculate the actual DUT impedance from your measured value. I do this routinely at HF, when I measure antenna impedance at the input end of a transmission line. Accuracy is best when the impedance being measured isn't far from the Z0 of the transmission line, and the transmission line is short. The longer the line and the greater the difference between line Z0 and DUT impedance, the greater the sensitivity to measurement error in both the measured DUT impedance and the line Z0 and length. A surprisingly small amount of line loss can also skew the measurements quite badly if Z0 and DUT impedance are quite different. If you need accurate results, you should do an error analysis to see how far off your calculated result can be, given the estimated accuracy of your measurement and calibration.

As I mentioned in my earlier posting, most people overestimate their ability to make accurate RF measurements. It's not at all trivial. Be sure to check your results frequently by measuring known load impedances close to the values being measured. How do you find the values of those "known" load impedances? Well, welcome to the world of metrology!

I apologize -- I read your earlier posting too hastily. Your antenna requires the full version of EZNEC because of the inductor. While a short inductor can be modeled as a lumped load, that doesn't work well in cases like this where the current changes significantly from one end of the coil to the other due to radiation. The coil has to be modeled as a helix.

A full model of your antenna with the coil properly modeled shows a feedpoint impedance of 5.03 - j212 ohms at 112 MHz over perfect ground. Loss in a real ground system will of course increase the resistance. It resonates at 171 MHz, where the feedpoint resistance is about 17 ohms. My result is far from your finding of resonance around 112 MHz, so maybe I didn't interpret the design correctly -- the antenna I modeled is a total of 11 inches high, the center 3 inches of that being the 1 inch diameter 5 turn coil.

With EZNEC and similar programs, you can only connect directly only to perfect and MININEC-type ground; connection to Real, High-Accuracy ground results in an unpredictable resistance that has no physical meaning. More information can be found in the Modeling Ground chapter of the EZNEC manual under Building The Model.

To tell the truth, I got the result for a wire over ground from an NEC-2 model, after first checking to make sure I got the theoretical 0.5 volt for the center of a dipole in free space. (NEC-2 has provision for applying a plane wave to the model.)

In the process of confirming the 0.5 volt value, I found an error in a popular text, Balanis, _Antenna Theory, Analysis and Design_. On p. 61, he incorrectly states that the current along a short dipole "can be assumed to be constant", which isn't true, and from that concludes that the "induced voltage" would be 1 volt when the dipole feedpoint is short circuited. How he defines "induced voltage" with a shorted feepoint isn't clear, but the uniform current assumption he used to get it is incorrect.

Kraus, in _Antennas_, and others get it right, and modeling confirms it.

Message-ID: <1133681998.929717.153920@o13g2000cwo.googlegroups.com>
Source record: 67031

A RF module was integrated with an application. The whole system including the RF module, antenna and application components must be put inside a plastic box (per the users' requirement). Unfortunately, the application components include a transformer and some other metal components, and the box (designed beyond my control) is small, and the antenna is very close to these metal comonents inside the plastic box (very little room inside the box). I found the RF performance (e.g. Tx/Rx distance) is much weaker than if the antenna is farther separated from the the other components (for example, let the antenna stick out of the box...). Could you make some suggestions or guidelines to deal with this situation so that the RF performance is as good as if the antenna is stick out of the box ....

Thanks for your help.

Jin

The non-uniform current does not arise from radiation but from the distributed capacitance of the wire turns on the helix to its surroundings.

Distributed inductance and capacitance of the helix behave as a short transmission line and there is a corresponding phase shift between one end and the other in addition to the non-uniform current distribution.

The effects can be estimated by approximate calculations with an adequate degree of accuracy but it requires the right type of computer program (which probably doesn't exist) to provide exact answers.

Reg Edwards wrote:
> Roy, you have anticipated my thoughts on the subject.
>
> Nevertheless, I will do some calculations.

You should be able to reason the wire-over-ground case as follows:

Imagine a plane wave of 2 V/m intensity striking a 2 m long open circuited dipole in free space. The open circuit voltage should be 4 times as great as it would be for a 1 V/m wave striking a 1 m long dipole. If you bisect the system with a ground plane, you have half the dipole and half the field above ground -- that's a 1 m wire and 1 V/m field. And half the original dipole's voltage appears between the bottom end of the wire and ground. So the resulting voltage is twice what it would be at the center of a 1 m dipole in free space.

> The proof of the pudding lies in the type of computer programs whose
> input data does not depend on unreliabe human imagination about

I have no idea what you're talking about there, but I'm sure that whatever it is, it must not apply to the programs you write.

> I have no access to the learned text books or computer programs.

Sure you do, as does anyone with access to this newsgroup. Texts are readily available by web order for the price of a very few bottles of mediocre wine. Some have even been scanned and posted on the web. And NEC-2 is free and can be downloaded from the web. But some people just can't deal with any idea they didn't come up with on their own -- we call it the NIH (Not Invented Here) syndrome. But each to his own.

Enjoy tonight's Balanis. You can save the Kraus for a special occasion.

Roy, I've seen your postings hereabouts over the years and you've
always struck me as one of the most knowledgeable posters on this,
the most technically-challenging of all hobbies.
I've recently bought a VNA and am going about the laborious process of
setting it up with precisely-cut interconnects to the T/R bridge. Next
thing I need to know is...
Say I have a mica capacitor (for example) that I want to check for its
SRF. How should I mount this component so as to minimize stray L&C
from anything other than the component itself? IOW, what 'platform'
(for want of a better word) do I need to construct to permit accurate
measurements of this cap's RF characteristics in isolation?
Thanks,
Paul

How about the fact that it is a *standing wave antenna* with a
forward traveling wave in one direction and a reverse traveling
wave in the other direction? The net current is the sum of
those two current components and their phasors are rotating
in opposite directions.

Doubt that too.

I can't find any data on this box, but it's likely that the
interconnects are carrying 1) the rf excitation out of the mainframe,
2) a signal from the referance arm of a bridge and 3) the
reflected/transmitted signal.

When calibrated, as I believe I described in another thread, errors
(if any) caused by the interconnects should wash out.

You must have the 1st edition. In the second edition Balanis says on page
133 that the current on an infinitesimal dipole can be considered to be
constant. On page 143 he says the current along a small dipole is
triangular shaped.

This depends a lot on what instrument you are connecting to this
coupler. If it's nothing more than a power sensor, then you are
making scalar measurements and phase is meaningless.

You would calibrate by placing a short on the measurement (antenna)
port and getting a 100% reflection reference (rho=1). You would
determine the magnitude of the reflection coefficient by ratioing this
to the measured value.

If you have a magnitude and phase sensitive instrument (vector
analyzer) then, as others have answered, you calibrate with additional
reference standards. In any event, the phase shift through the
coupler is compensated for by the calibration process.

>
>Do bi-directional couplers automatically compensate for frequency shift?

No. The provide for a simultaneous sample of the forward and
reflected signals.

Wes,

Your answer to the question about bidirectional couplers was they do not compensate for phase shift. Let me ask it again:

Do the measuring ports of a bi-directional coupler accurately represent or preserve the relative phases of the signal?

To put it another way is the phase shift of the driving and reflected signals changed by the same about?

Thanks - Dan kb0qil

If you were to make the antenna a ground plane or vertical and use a piece of copper clad circuit board as the plane, it might provide a good degree of isolation from the other components below that plane.

Richard,

Terman said no such thing, and your interpretation is clearly in error.

Magnetic fields cannot impart ANY energy to charges, such as electrons in a wire. This is because the force from a magnetic field on a charge is always perpendicular to the motion of the charge. No work can be done by the magnetic field, and the energy of the electrons does not change. Only electric fields can provide energy to an electron.

Fortunately, Faraday's Law saves the day. Changing magnetic flux is inextricably intertwined with electromotive force. Terman's comment on page 2 of the 1955 edition simply points out the operation of Faraday's Law. (Yes, I have this volume of Terman.)

Your conclusion statement is completely reversed. The magnetic field does nothing to induce current in the antenna, while the electric field does everything.

Again, however, the laws of physics save the day. Maxwell's equations link electric and magnetic fields in such a manner that the magnetic field you favor creates just enough electric field to drive the electrons in the wire.

As has been stated many times in this newsgroup, it is not possible to filter out one field component or the other. As long as there is some time dependence, i.e., other than purely static fields, both the electric and magnetic fields coexist.

4150. Ferrite rod antenna theory

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-04 17:39:39 UTC
From: John Popelish <jpopelish@rica.net>
Message-ID: <jsKdnVthIOC8tA7eRVn-tg@adelphia.com>
Source record: 67047

I am working through the design of a ferrite core antenna with a necked down center section. I am trying to calculate how much permeability is needed to get most of the available signal out of the antenna, compared to that needed for a cylindrical rod.

I think that for a full cylinder of material to be a lower reluctance path than the same volume of space, the relative permeability just has to be higher than 1. If it is much more, then considerable additional flux will be gathered around the ends of the cylinder (that would not have passed through the cylinder's volume of free space).

If the rod consists of large diameter ends and a thinner central section, then the permeability of the long center section must be higher by the ratio of the (end area)/(center area), for the same assumptions to hold.

For instance, the present design has end diameters of 2.4 inches and a center diameter of 0.5 inches. So the center section needs a permeability (2.4^2)/(.5^2)=23 times higher than would be needed for a solid 2.4 inch diameter cylinder the same overall size to pass about the same flux in a given field.

Is this reasonable?

The phases seen at each coupled port should be identical to the phase of the forward and reflected signals. This is easily verifiable, and frequency independant, as follows:

No load -- forward and reverse amplitudes equal, and in phase;
Short circuit at output -- forward and reverse amplitudes equal, and 180 degrees phase difference;
50 ohm load -- reverse < than forward by <= specified coupler directivity, and phase difference can 0< theta < +/ 180.

This is only true if the frequencies are low enough such that the standards do not require quantification by the use of "Standard definitions" -- see www.vnahelp.com.

Great! It sounds like you have it well planned. I was afraid you were
one of those fellows who thought it is a trivial problem.

I have a little experience(old) in ATV on 439 and current experience
in RC.
You have probably already planned for these things but let me share
observations:

All antennas with gain have reduced bandwidth.. a TV signal without
sound requires at least 4mhz without degradation.

All antennas with gain have reduced beam width. A little yaw with
anything resembling a yagi is going to be very noticeable.

It is easier to get gain at the receiving end than the transmitting
end. My 48 element collinear was very wide band and measured 21 db
gain. It is 3X5 feet.

Good luck, John Ferrell W8CCW

PS, AMA insurance specially excludes autonomous flight.

Hi Paul,

Accuracy and precision is no good unless you can duplicate the test rig to the eventual environment of use. That said, precision capacitors and inductors are three leaded devices. The third lead goes to the shield around them. Obviously for either, a shield changes what would have been the nominal value for the component. However, that change also swamps all the variables that could disturb the accuracy. In other words, the shield enforces a fixed environment that reduces all other stray influences to a minimum.

In so doing, I've been able to measure standard capacitors and inductors out to 9 places. Without those third lead configurations, the same components would easily lose 3, 4, or 5 of those digits.

So one way to mount a mica cap would be over and close to a ground plane that extends beyond its foot print by a significant distance. This proximity would swamp the effects of other components nearby causing a shift in the resonance (if and when they were added, or removed). Building a cage around the capacitor would reduce these effects even further. Of course, all such measures would shift the native resonance, but you are never going to achieve that frequency anyway.

You can, of course, elect to go the other way with a minimal ground proximity. In that case you would use microstrip techniques to build the test rig, making the strip with equal to the width of the component (presumably being surface mount). However, SRF becomes rather meaningless except as a general indicator. This is because changing the board material from alumina to epoxy; or changing from a series to shunt application can shift this frequency by 20% to 40%.

Another issue is with the leads themselves. ESR for caps can easily tally up to a tenth of an Ohm and you have to select your caps on this basis as much as for their inductance. In this regard, you measure the D of the cap (dissipation factor) not Q (although each is the inverse of the other, there are D instruments specifically for this).

This tenth Ohm is NOT necessarily in the wire lead (a common misconception) but rather in all the parallel (or worse, series of the wrapped cap) plate connections. For surface mount caps, you may want to mount them 90ï¿½ (up on edge rather than flat on face) to the board to double the first PRF resonance and reduce the insertion losses there and above.

The short answer to your question is how stable, and how accurate do you want to reproduce the measurement to your application?

dansawyeror wrote:
> Do the measuring ports of a bi-directional coupler accurately represent
> or preserve the relative phases of the signal?

Let's look at a typical SWR meter sampling circuit. The current is
sampled by a one turn primary on a ferrite toroid. The voltage is
sampled by a tap on the line close to the point at which the toroid
is mounted. At HF frequencies, a wavelength is so long compared to
that configuration that physical sample point errors are usually
considered to be negligible. That obviously changes at UHF+.

No coupler 100% preserves the relative phases. The question is:
What is the accuracy? For any configuration, a worst-case accuracy
can be specified. At 4 MHz, it's not a problem. At 4 GHz, it's a
big problem. At visible light frequencies, most don't even try.

Frank,

The bi-directional coupler is a machined block about 1 x 3 x 5. The inside is a straight through line, the pickups are simply terminated one loop lines. It is a UHF coupler that works reasonably down to 2 meters. When I configure this to look at the forward and reflected 'open' circuit case they are not in phase. Reflected lags forward by about 40 degrees. (I checked the connection delay and this is not a cable issue.) This is frequency independent. Shorting the output reverses this relationship. The outputs are terminated in 50 Ohms so I conclude it is a 50 Ohm device. When I terminate the device in 50 Ohms the forward and reflected outputs are out of phase by about 140 degrees.

What is the significance a non frequency dependent phase shift between forward and reflected? This shift is frequency independent.

Thanks - Dan kb0qil

What I suggested is to use the copper separation between the antenna and
the other components where it can act as a shield, and to integrate the copper
as part of the antenna -- i.e. it becomes the ground plane for a vertical element which
is your radiator.

Thanks for your vote of confidence. But on the topic of network analyzer measurements, I gladly defer to Wes Stewart, Tom Bruhns, and other posters who have spent much more time making real-life measurements with them than I have. I've used them from time to time, and for some really challenging measurements, but not by any means as much as those folks have.

In general, you minimize stray inductance by keeping leads short, and capacitance by keeping conductors apart. The ideal setup is a coaxial environment right up to the DUT, but even that is subject to coupling around the DUT, both from one terminal to the other and from each terminal to ground. If possible, the best plan is to calibrate out the strays. That's a science and art in itself, and I'll have to yield to people with more experience than mine for practical information about how best to do this.

The effect of the strays depends heavily on what you're measuring. For example, if you're measuring a low impedance, you can get by with more shunt C than if you're measuring a high impedance. If you're measuring a high impedance, you can tolerate more series inductance than when measuring a low impedance. So when you inevitably find that you have to

make tradeoffs in designing a fixture, the trades you make will depend on what you expect to measure.

The posts refer to two different couplers, the first posting is in reference to a Mini-circuits ZFDC-1-3. The last posting is in reference to a bi-directional coupler as described. At this point the objective is to 'learn' as much as possible about the operation of couplers.

Did you also receive a calibration kit with the VNA? If you did so, then the lengths of these interconnect cables are not crucial for calibrated measurements. Only uncalibrated measurements will be affected.

It would help to know the manufacturer and model of the VNA.

4162. What is a duplexer, diplexer and combiner?

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-05 02:50:30 UTC
From: crb <anon@net.com>
Message-ID: <dn09hk02r2p@enews1.newsguy.com>
Source record: 67059

What are the functions of each of these?

Are they used on TX or RX circuits?

I know a cell site uses a duplexer so that it
has an extra RX antenna for diversity. How
does this work? Is the duplexer on the antenna
that transmit/receive combo antenna notching
out the TX frequency so the receiver doesn't get
overloaded by it?

> Yes, and you didn't believe it when you saw it.

Your memory is slightly faulty. What I objected to was Dr. Best's assertion that 75w + 8.33w = 133.33w. It still doesn't, never did, never will, and violates the conservation of energy principle. What Dr. Best apparently failed to realize is that the extra 50 watts of energy required to balance that energy equation does NOT come from waves P1 and P2 but instead comes from wave cancellation of waves P3 and P4 on the source side of the match point. Wave P1 contains 75 watts and Wave P2 contains 8.33 watts. Without a source of constructive interference energy, they cannot add up to 133.33 watts. That source is destructive interference energy, -2*SQRT(P3*P4), from the source side of the match point which supplies the +2*SQRT(P1*P2) constructive interference energy to the load side of the match point where (P1*P2)=(P3*P4). At an impedance discontinuity in a transmission line, far away from any source, all constructive interference energy must necessarily be balanced by an equal magnitude of destructive interference energy in order to satisfy the conservation of energy principle.

This is all explained in my "WorldRadio", Oct./Dec. 2005 articles. Unfortunately, most of the Greek letter Thetas didn't make it through the conversion process and wound up as underline marks. Part I is already on my web page under "The Rest of the Story" along with a couple of remarks about forward power, reflected power, superposition, and interference. Part II will appear on my web page after Christmas.

> the pipe have on the radiating wire?
>

*Install the pipe.

*Build a 16-17 foot tapered radiator made from telescoping lengths of
6061-T6 aluminum tubing. See the Texas Towers site for the tubing.
E-mail me about doing the design of the radiator, I'm equipped to do
the FEA stress analysis.

*Build an aluminum adapter plate to attach the radiator to the pipe.
See any "how to" type ham antenna book which includes the construction
of yagis. Use a pair of stainless steel u-bolts to attach the adapter
plate to the pipe. Use a pair of insulated clamps to attach the
radiator to the adapter plate. These are available from DXengineering.

http://www.dxengineering.com/Sections.asp?ID=1&DeptID=21#Top

*Run ONE 16-17 foot wire to the the adapter plate but do not ground it.
Instead attach it the braid of the coax. Attach the radiator to the
center conductor of the coax. Pull the "radial wire" as far away from
the trailer as possible in some direction or another.

This arrangement would give you a "sorta" inverted L or vertical dipole
type antenna instead of a ground plane.

Asimov wrote:
"An antenna is just a stationary probe in a moving E-field."

Along some path in space there is an electric current which is changing. It is growing or it is shrinking. It is not constant..

This current as a result of its changes radiates electric and magnetic flux. The electric flux lines are are perpendicular to the current path. The magnetic flux lines encircle the current path. The flux is moving away from the current path at the speed of light. At a distant point these electric and magnetic flux lines arrive because they sustain each other during their long trip.

There is an initial wavefront. It started as a spherical wavefront but has traveled so far that for practical purposes it is now a plane wave. In the wavefront there is an electric force which would attract or repel electrons but it has the same strength everywhere over the arriving wavefront. Therefore, wlectrons in a wire parallel to the wavefront are not moved along its length by the electric force. This force would only tend to move electrons from one side of the wire`s diameter to the other side of the same diameter. Our interest is in current along the length of the wire.

However, the magnetic lines of force are sweping at the speed of light across the wire which parallels the wavefront. If the wire also parallels the direction of the current which generated the lux (is correctly polarized), it will experience a voltage induced all along its length. This induction is totally a result of the magnetic field.

There are some serious errors in this explanation.

1. The source is not an "electric current which is changing". There is an EM field made up of photons. There are two theories describing this, one is a wave theory and the other is a particle theory. Neither one completely enplains the phenomenon.

2. There is no current and therefore there is no "current path".

3. The E and H aspects behave similarly, both are changing. The E domain is no different in that respect then the H domain. The E portion of this particle/wave phenomenon is as capable of transforming into a useful signal in the antenna the H portion is.

Antennas can be either E devices or H devices. E devices respond to the electric dimension and create a signal while H devices respond to the magnetic dimension and create a signal.

There is a time varying voltage gradient in the E field too. Turn the
wire around 90" then to find the E gradient. If the wire length is
such that one end is positive while the other end is negative then
charges will flow inbetween both ends.

Anti-static spray won't work on an antenna.

I'm not sure I understand the question(s) but in the case of a vector
reflectometer using a dual directional coupler maybe this will help.

Here is a dual directional coupler.

```
Reverse Forward
| |
| |
|----------R R ---------|
X X
Input --A----------------------B--C Load
```

Let's say that at frequency, F, the coupling factor (X) is -10 dB with
no phase shift between point B and the forward port and between point
A and the reverse port to keep it simple.

So a wave propagating in the forward direction (Input --> Load)
induces a signal at the forward port that is 10 dB below the input at
0 degrees phase with respect to point B. A wave propagating in the
opposite direction has the same relationship at the reverse port; 10
dB down and 0 degrees phase with respect to point A.

A to Reverse and B to Forward -might- track reasonably well in both
magnitude and phase, but in this case, it's immaterial.

Because B-A and C-B > 0 there will be a frequency dependent phase
difference between A, B and C.

When we calibrate using a short on the load port here's what happens.

The signal at the forward port becomes the reference, i.e., unity amplitude and 0 degrees phase.

The short creates a 100% reflection and -180 degree phase shift. This signal propagates back down the main line to the source, which is assumed to be a perfect match, so there is no re-reflection. A -10 dB sample (by definition: unity) is coupled to the reverse port, with a phase shift, theta(F), determined by the electrical length of the line C -> B -> A.

Unless we are lucky enough to be Lotto winners, the signal at the reflected port -will not- be 1 @ ang-180 deg. So our calibration routine must do whatever math is necessary to make the ratio B/A = 1 @ ang-180. This fudge factor is then applied to all subsequent measurements to "correct" the data.

Now to address (I think) your question. If we change frequencies, theta(F) changes and the fudge factor no longer corrects for it. While the coupling factors might track, it is of little consolation because the calibration is good only at the frequency where it was performed. Automatic network analyzers perform calibration at each test frequency, or at least enough points to interpolate between.

Without the 2*SQRT(P1*P2)=50w constructive interference energy,
75w + 8.33w will *NEVER* add up to 133.33 watts. Dr. Best's
equation, 75w + 8.33w = 133.33w, is superposition of powers
which is not allowed AND a violation of the conservation of
energy principle. You don't really support superposition of
powers and violations of conservation of energy, do you?.

If you furnish exactly 75 watts and your neighbor furnishes
exactly 8.33 watts, can you power a 133.33 watt device?

Gene, W4SZ wrote:
"Terman`s comment on page 2 of the 1955 edition simply points out the operation of Faraday`s Law."

Faraday`s law says that, while the magnetic flux linked with a closed path loop or coil is changing, the closed path is the source of an electromotive force (voltage) whose magnitude depends only upon the rate of change of the flux through the path.

If we cause an antenna to be surrounded by an altrernating magnetic field, a voltage will be induced in the antenna in accordance with Faraday`s law, This induced voltage is necessary and sufficient to account for all of the energy received by the antenna.

Hi Jim,

I was going to try to stay out of this recurring silliness, but since you accidentally pulled me in I will add my spin.

The only mistake made by Steve Best was allowing himself to get dragged by Cecil into the intellectual landfill. Yes, most people with rudimentary arithmetic skills would agree that 75 plus 8.33 does not equal 133.33.

However, anyone even remotely familiar with waves would readily understand that the component waves Cecil loves to talk about are merely mathematical conveniences. It is entire possible to set up other model configurations, such as a combination of a one traveling wave and one standing wave.

In order to make his model work, Cecil needs to invoke the mythical P3 and P4 on the source side of the reflection discontinuity. He never gets around to explaining how these two waves, which exactly cancel at all points in space and at all times, can contain any energy at all.

The reason that most practitioners of wave models solve for the fields first and then worry about power or energy is:

a - This procedure works correctly all the time.

b - It avoids the problems created by analyzing fictitious extra components added for mathematical convenience but containing no physical reality.

I do not expect to change Cecil's mind. Other than his own potential embarrassment from the silly publications in World Radio, his folly is harmless.

73,
Gene
W4SZ

Crb,

These are basically filters. The terminology varies sometimes
for "diplexer" and "duplexer", and they are both used to describe the same
or different things. I'll give the way they are used in my field - two-way
radio and cell phone systems.

Duplexer:

When we transmit and receive at the same time, this is called duplex
operation.

A duplexer is designed to allow a transmitter and receiver (operating at
slightly differing frequencies) to use the one antenna at the same time.
There are several things that must be taken care of in this situation.

1 - The transmitter energy must be kept away from the receiver or it will
burn things up.

2 - The transmitter signal can still cause trouble if it is not lowered a
lot more than this "blow-up" level. The undesirable effects are commonly
intermodulation (mixing of the transmit signal with near-by transmitters
which then causes signals which interferes with other receivers) and
spurious responses (mixing of the transmitter signal with more distant
transmitters which cause signals that interfere with this receiver).

3 - Transmitters also put out noise as you move away from the carrier and
this must be reduced to where it does not cover up the desired signal in the
receiver.

As you probably understand, the difference between the
transmitted power and the received signal strength is very great and
typically around 170 to 190 dB.

To get #1 and #2, a filter is placed in the receive line which passes the received frequency with little loss, but attenuates the transmitter power to a level which keeps the IM products to an acceptable level. To get #3, a filter is placed in the transmitter line which passes the transmit frequency with little loss, but attenuates the noise (and any other spurious which may be there) which the transmitter is producing on the receive frequency. These filters can be band-pass or band-reject (notch) filters.

Diplexer / Combiner:

These two terms usually refer to devices that allow two transmitters to use one antenna at the same time. However, the term "diplexer" and "duplexer" are used differently in some circles. There are several ways to do this.

The term "Combiner" is most common in cellular telephone systems, the term "diplexer" is more common in the military.

Combiner:

One method (used in cellular transmitters) uses narrow band filters (commonly called cavities). One filter is on the output of each transmitter and, obviously tuned to that transmitter's frequency. Then, to allow these to be all connected at one point so one antenna can be used, transmission lines are used in a special way. These lines are made special lengths such that the following happens.

We will consider only two transmitters on two different frequencies here "A" and "B".

We look at the junction point where the two filter lines connect to go to the antenna.

At frequency "A", the transmission line from filter "B", transforms (rotates around the Smith chart) the impedance of filter "B" such that it is a very high impedance at the junction point. This high impedance across the 50 ohm transmission line accepts little power and therefore disturbs things very little. This means that the power from transmitter "A" only goes to the antenna and not back into transmitter "B".

For transmitter "B" just switch the A's and B's in the above.

The logical extension of this is for multi transmitter systems where the transmission lines are made such that all filter / transmission line combinations, other than the one frequency going through, appear as a high impedance at the junction.

Systems use this technique to connect as many as 20 transmitters to one antenna and the frequencies are quite close together - in the same band.

This is a narrow band system and must be re-tuned if the transmit frequencies change.

The further apart the frequencies are, the easier it is to make this device. With widely differing frequencies such as 144 MHz and 450 MHz, this

can be done with simple low pass and high pass filters.

Diplexer:

Again I remind you that some use the term "diplexer" and some use the term "duplexer".

I believe diplexers are commonly band-pass filters. Using band-pass filters, we can allow the transmitters to move around a bit. I have seen things called diplexers used where the transmitters are in different bands (like 150 MHz and 450 MHz.). There must be the same consideration that I describe above for the impedance at the junction end of the transmission lines coming from the filters where they connect to the common junction point.

Finally, because these are filters, they can be used in receive as well as transmit lines. With a two way radio that operates in two bands but only uses one connector - say 144 MHz and 450 MHz. you can use these devices to connect two antennas to the radio, one antenna for 144 MHz and one for 450 Hz.

You can also connect two radios, one operating at 144 MHz and one at 450 MHz to an antenna that operates on either band.

You can also connect these two radios to a common feed line with a diplexer and then use another diplexer (facing the "other way") to feed two separate antennas for the two frequencies.

In the diversity situation you mention, the duplexer saves one antenna that would be needed for transmit by using one of the receive antennas for both receiving and transmitting (duplex). Some systems don't use a duplexer here and do have three antennas. Two for dual diversity receive and one for transmit. You may be able to see this as three vertical bars (antennas) on each side of the triangular top of some cell towers.

Hope this helps.

Some questions about a 140' dipole fed with ladderline from an unbalanced tuner to work 160-10m:

1. Does it matter if the balun is placed on the tuner output, or at the dipole center feedpoint?

2. Which type of balun (voltage/current) would be best for centerfeedpoint
use?

4. What ratio balun would be optimal for either application?

A balun placed at the dipole center feedpoint has BALanced
ladder-line on one side and the BALanced dipole on the other,
both of which are balanced. So why on earth would anyone attempt
to install a BALanced to UNbalanced device at a point where only
balanced environments exist?

> 2. Which type of balun (voltage/current) would be best for
> centerfeedpoint
> use?

What you need is a BALBAL. Good luck on finding one at a decent
price that works with the impedances you will encounter.

> 4. What ratio balun would be optimal for either application?

A Balun should only be installed at a BALanced to UNbalanced
discontinuity. Forget about trying to install them anywhere
else. Most hams who understand what they are doing use a 1:1
choke-balun at the BALanced to UNbalanced point. Take a look
at my 130 ft. all-HF-band dipole (click below)

Gene, W4SZ write:
"As has been said many times on this newsgroup, it is not possible to filter out one field component or the other."

Saying it does not make it so.

Countless Faraday screens are at work removing the E-field component from electromagnetic waves. Faraday said that the voltage in a coupled circuit depends only on the rate of change of the magnetic flux through the circuit. He was refering to induced voltage. It was 1831 when Michael Faraday observed the interaction between primary and secondary coils in what was likely the world`s first transformer. Faraday made it himself and noted that the needle of a galvanometer connected across one coil deflected briefly whenever he connected or disconnected a battery across the other coil.

it is just as easy to remove the H-field from the wave as it is to
remove the E-field with a Faraday screen.

To remove the H-field, one sure way is to completely enclose two coils
so they are completely shielded from each other and all electromagnetic
waves. Put the coils in separate metal cans. Put a tiny hole in each
can. Conect one termial of each coil to its end of a coupling capcitor.
Ground the other terminal of each coil.. Ground is the return path for
the coils but it must run on the surfaces of the cans and through the
tiny holes due to skin effect.
Complete shielding removes the H-field as a coupling agent. Only E-field
coupling is provided via the coupling capacitor.

Best regards, Richard Harrison, KB5WZI

I should have said Tom. If I were Cecil I'd have blamed the error on my glasses or my advanced age. ;-)

> You don't really support superposition of
> powers and violations of conservation of energy, do you?.

Depending on how high you keep your squelch set, you should already pretty well know what I think about those things.

You're at least partially right though. Power does not superpose (because, for among other reasons, it doesn't move or propagate). The point you continue to miss is that power does not interfere either. Nor is it valid to take the square root of the product of two power numbers and claim that it turns around miraculously and goes the other direction. But that's what you've miguidedly presented to the readers of World Radio as fact. The irradiance equations are nevertheless correct because power goes as the square of the fields - which do of course superpose and interfere. The equations accurately describe the effect - the end result, the outcome, not necessarily the cause or the mechanism by which the result is achieved.

Before we go any further (and it is my sincerest hope that we do not), I agree with Melles-Griot, Born and Wolf, Hecht, Jackson, and the other E&M and optics books. What I disagree with (and I'm sure given the opportunity so would the above mentioned authors) is some of your interpretation of the physical phenomenon they describe.

Too bad Dr. Best posted the equation: "Ptotal = 75w + 8.33w = 133.33w"
on this newsgroup (and, thank goodness, left it out of his article) so
he obviously disagreed with you at the time. He also said that interference
had nothing to do with it.

> However, anyone even remotely familiar with waves would readily

What happens at an impedance discontinuity given those circumstances? To
find out, read my WorldRadio article, Part I of which is posted on my web
page. Part II will be posted after Christmas. At the risk of raising your
politically incorrect ire as I have done with this technical posting,
MERRY CHRISTMAS!.

> In order to make his model work, Cecil needs to invoke the mythical P3
> and P4 on the source side of the reflection discontinuity. He never gets
> around to explaining how these two waves, which exactly cancel at all
> points in space and at all times, can contain any energy at all.

The answer is simple. Do waves contain any energy at all? Do waves that
cancel contain any energy? If waves contain no energy, they cannot exist,
and therefore are incapable of canceling. If they exist and cancel, they
contained energy just before their cancellation. Any way you cut it,
my approach is consistent with the laws of physics as enumerated in "Optics",
by Hecht, and yours leads to a contradiction of those laws of physics.

> The reason that most practitioners of wave models solve for the fields
> first and then worry about power or energy is:
>
> a - This procedure works correctly all the time.

Yes, it does. But optics engineers didn't have the luxury of dealing
with voltages and currents. They had to solve the problem using powers.
And they did exactly that decades ago. That RF engineers refuse to
consider the laws of physics concerning EM waves developed by optics
engineers is absolutely astounding to me. W7EL put it best, something
to the effect that if it wasn't invented here, we don't want to hear it
(even if it is right). But I daresay that Eugene Hecht knows much more

about EM waves that you will ever know, given your closed mind.

> I do not expect to change Cecil's mind. Other than his own potential
> embarrassment from the silly publications in World Radio, his folly is
> harmless.

You are just displaying your extreme ignorance, Gene. My "WorldRadio" article corrects some of the *conceptual* errors in Dr. Best's QEX article but otherwise contains the same equations as his article. If you disagree with me, you are also disagreeing with Dr. Best's equations, i.e. you are between a rock and a hard place.

It is interesting that the very people who tell us not to worry about energy are the people who get so emotionally rabid when someone chooses to worry about energy like real-world physicists do. What do they possibly have to lose besides face, self-esteem, sleep, and their pseudo-religious guru status? :-)

Alzheimer's can certainly strike at your age, Jim. :-) My Dad was
legally blind when he was my age so I'm ahead of the curve.

> You're at least partially right though. Power does not superpose
> (because, for among other reasons, it doesn't move or propagate). The
> point you continue to miss is that power does not interfere either.

Here's a quote from my magazine article, Jim. If you would just cease
and desist from your MF'ing ways (that's "mind", not "muther"), you
might understand. Quote:
****
"The words 'power flow' have been avoided even though
that is a term of common usage. For the purposes of this paper, energy
flows and power is a measure of that energy flowing at a fixed point or
plane. Likewise, the EM fields in the waves do the interfering. Powers,
treaded as scalars, are incapable of interference."
****
But you already knew that's what I believe since I have been telling
you exactly that in CAPITAL LETTERS for years now and even sent you
an advance copy of my magazine article. I have never asserted the things
you claim that I have. Hopefully, the readers will recognize you for
what you are.

> The irradiance equations are nevertheless
> correct because power goes as the square of the fields - which do of
> course superpose and interfere. The equations accurately describe the

> mechanism by which the result is achieved.

Where does the constructive interference energy come from, Jim? Hecht
says that in the absence of energy from other sources, the constructive
interference energy must be exactly matched by an equal amount of
destructive interference. Please present your credentials that allows
you to disagree with Eugene Hecht?

> Before we go any further (and it is my sincerest hope that we do not), I
> agree with Melles-Griot, ...

No you don't, and your disagreement is more than obvious to any informed
casual observer. You remind me of a fellow employee from the 70's. I asked
him what he would do if his wife caught him in bed with his neighbor's wife
(as I did) and he answered, "I'd just deny it."

Did you really?

It is unlikely that your proposed antenna system (140' dipole + bal un
+ coax) feed will provide acceptable losses on many bands, possibly
only one band.

You have given almost no detail of the antenna (and a key element of
the detail was in error), so it is hard to give more a more exact
information.

If you hadn't mentioned the feed line type, readers would probably
have sensibly assumed open wire feed as it is much more likely to be
feasible than coax feed of such a multiband dipole.

The article at www.vk1od.net/LOLL/index.htm shows in Fig 1 and Fig 1a,
antenna system losses for an antenna system comprising a low 66'
dipole and coax feed over HF. Your 140' (I am not sure why you didn't
nominate 133' which would be resonant on 80m for simplified / lower
loss coax feed) would be very roughly a frequency scaled version of
the same thing.

Sounds to me like you are trying to fit the wrong antenna into the
wrong space.

Can you put radials in/on the ground? Can they be longer than 8 feet then?

And finally, can you put up a dipole or other wire antenna? If so, your
wife isn't going to be too happy when she sees the cost difference
between the dipole and what you already spent on the vertical. Dunno if
you have many trees in your area or not. But a dipole can be pretty
good, esp if money is tight. I have both a dipole (OCF) and a vertical.
They both work better than each other.... at certain times. 8^)

ALso, what bands are you trying to run?

I have no trees, streelamps, telephone poles, or anything higher than a 7 foot trailer. That was why I was considering a vertical. For practical purposes anything higher than 40 feet is forbidden and 25 foot is as high as I practically dare do. From what I understand, dipoles are not effective below 1/2 wavelength above the dirt, but verticals can work well fairly close to the dirt if they have to. From what I hear inverted vees are slightly better than dipoles but slightly worse than verticals at low altitude.

My wife really doesn't care about money as much as she cares about waste. If I can make my setup working with the stuff I already bought then great... At this point I am considering just throwing in the towel and raising a 20 foot iron pipe to mount a 20 meter inverted vee... sigh.

20m is my favorite band, followed by 40 then 30.

Vertical is probably the way to go for you.

> From what I understand,
> dipoles are not effective below 1/2 wavelength above the dirt,

Almost true. The (misnamed?) takeoff angle of a vertical antenna is
usually lower than a dipole that is lower than optimum. However, if the
vertical is not terribly efficient, it may not work as well as a dipole
that is more efficient. That is Why I think TOA is a misnomer. Antennas
radiate in all directions. It's just that the signal strength is higher
or lower at certain angles.

Cecil,

If this is name-dropping poker, I'll see your Hecht and raise with J.D. Jackson and Born & Wolf.

But thanks for the education. After 40 years of obtaining multiple degrees in physics followed by working R&D in the optics field I guess I still need to seek out some "real-world physicists" to figure out that energy is indeed something to "worry about". I never would have imagined such a thing!

Richard,

OK, I will turn this right back at you. How do you know that the
countless Faraday screens remove the E-field component from
electromagnetic waves?

"Saying it does not make it so."

Yes, I understand they are used in broadcast transmission lines, and
yes, I understand they take many lightning hits.

Faraday screens are effective. How do you know that they also negate the
fundamental properties of time-varying electric and magnetic fields as
expressed by Maxwell's equations?

Please post any contradiction of Hecht by your sources. That argument could get very interesting. To summarize: Constructive interference energy must come from somewhere in the real world. You seem to disagree. So where do you think constructive interference energy comes from?

> But thanks for the education. After 40 years of obtaining multiple

That's a really strange thing to admit, Gene, since a very large percentage of the physics community is dedicated to understanding where the energy was, is, and will be - down to an almost infinitessimally small amount. You definitely seem to be cast in the mold of the priests who put Galileo under house arrest. Are you comfortable with that position?

A short while ago, I explained why your Faraday cage doesn't separate E and H as you claim. Exactly the same explanation applies to this structure, but with E and H reversed. It locally modifies the E/H ratio but doesn't separate the field components and it certainly doesn't remove the E field as you claim.

Roy Lewallen, W7EL

I couldn't agree more, but that's exactly the topic from which you tried
to divert attention in your posting. Here's what you said:

>"I guess I still need to seek out some "real-world physicists" to
> figure out that energy is indeed something to "worry about". I
> never would have imagined such a thing!"

If you don't worry about energy, you have nothing to add to the discussion.
If you do worry about energy, please read my "WorldRadio" article which
tells you more than you (and others) ever wanted to know about energy in an
RF transmission line.

I can only assume that if you are still asking that question 6 hours
after I wrote you a response, that you didn't read / understand the
response and the referenced article!

If that was too hard to understand, the short answer is NO. If you
want to understand why, go back and read my earlier posting and the
article.

> Sometimes (back then, and maybe still), one could by tech books from China
> that was on almost tissue paper pages. They were quite cheap.

You can find people on Amazon.Com selling books this way. The books themselves often have stern warnings about how they're only licensed to be sold in specific countries such as China or India, although personally I have a hard time feeling too sorry for the publisher if the purchaser really is someone trying to get an education and not the librarian of a well-funded company who's stocking the corporate library.

(I could also whine about how most public libraries today seem to have incredibly poor selections of _contemporary_ technical books, but I suppose that with their limited budgets purchasing the newest romance novel for $10.99 does generate a lot more checkouts than purchasing the re-print of Grover's Inductance Calculations...)

It's interesting that educational textbooks in the USA tend to cost pretty much the same as 'professional' texts (e.g., those from Artech house) or more (e.g., more of the technical texts from Dover are quite inexpensive) whereas the software industry figured out a long time ago that it's better to sell students, e.g., a stripped down $99 version of Office than have them pirate the $799 professional version. As it is, very few students keep their textbooks at the end of their classes, which I think is rather unfortunate... although I would admit that many people who become, e.g., EE's today truly never expect to crack open Cheng or Sedra & Smith (or even Horowitz & Hill!) for their entire careers.

In the past decade, I've found some very good, reasonably priced self-published book or eBooks, such as those on Peter Joseph's site. (In fact, I still wish I could find out whether or not John Pastonek ever published anything besides his RF oscillators short course book -- in the back of the book he claims there either are or would be others, but he seemed to have dropped off the fact of the earth.)

Roy Lewallen, W7EL wrote:
"A short while ago, I explained why your Faraday cage doesn`t separate the E and H fields as you claim."
n
I am misunderstood. I never used the tem Faraday cage. I understand the Faraday cage to be a completely shielded enclosure which could be a metal automobiole body, a steel rebar reinforced concrete structure or a screened room. These all tend to completely block both the E-field and the H-field components of an electromagnetic wave.

I gave an example of the metal rakes (Faraday screens) used at the medium wave broadcast plants where I worked. The function of the Faraday screen was primarily to eliminate capacitive cooupling, and thus the E-field between the transmission line and the antenna. This reduces harmonic radiation. It adds expense and complexity but is worth the price for lightning suppression if for nothing else.

Most Faraday screens are used at powerline frequencies to eliminate capaacitive coupling between primary and secondary of a power transformer.

I checked the internet for a recent posting and found an article by arnie@radiohc.org who wrote: "Beware, this cannot be an auto-transformer. It must be a transformer with two completely isolated windings, and with a Faraday Screen wound between the two."

Why would one pay a lot of extra money for a transformer which eliminated capacitive coupling if it didn`t work, especially in Havana, Cuba?

Best regards, Richard Harrison, KB5WZI

> be more expensive than the pipe itself?

It's not "pipe", it's thin-walled very light weight high-strength
aluminum TUBING. which is about as "exotic" as CW in ham circles. Don't
ask us what the shipping costs would be, push back yer keyboard and
dial Texas towers @ (800) 272-3467 and ask them.

As to your problem with hundred-mile round trips to your nearest Home
Despot store: I have two of 'em 15 +/- minutes from here and except
for some occasional stainless nuts, bolts and cheap wire they're
useless as far as decent sources of antenna materials go.

The Mother of All REAL Hardware Stores is McMaster-Carr. 3,000 + page
of industrial-quality bits and pieces which make great antenna parts
only a phone call away. They have staineless u-bolts on top of
stainless u-bolts, aluninum stock for adapter plates, all of it . .

http://www.mcmaster.com/

(330) 342-6100 for help with finding what you want if their website
catalog comes up overwhelming.

If you're averse to online purchasing that's OK, order all your antenna
"stuff" by telephone, then sit on yer butt and wait to have it dropped
on you by UPS or FedEx within a couple days at most.

Ditto DXengineering: (800)-777-0703

> That's not negative, that's practical!

You have problem with your priorities and what's up out here in
practical ham antenna realities.

Gene, W4SZ wrote:
"How do you know that they also negate the fundamental properties of time-varing electric and magnetic fields as expressed by Maxwell`s equations?"

I did not make that claim.

Pits from the lightning strikes are evidence that the voltage gradient is high between the coil and the Faraday screen. The second coil is clean, not pitted.

I explained the operation of a Faraday screen earlier but was misunderstood so I`ll quote a professional writer and consulting engineer, B. Whitfield Griffith, Jr. who writes on page 246 of "Radio-Electronic Transmission Fundamentals":

"It is often desirable and practical to allow one type of coupling between circuits and eliminate the other. Figure 28-1, for instance, shows two coils which are coupled but have a special type of shielding between them that causes the coupling to be purely inductive and not capacitive, This shield consists of an array of parallel wires which are grounded at one end only. The lines of electric force from the coils terminate on these grounded wires, so that there are no electric lines of force passing from one coil to the other and hence no capacitive coupling. On the other hand, since the wires do not form closed loops, there is no circulating current in the shield and therefore nothing to stop the penetration of the shield by the magnetic field. This type of shield has long been known as a Faraday screen. It is important that the capacitive coupling be eliminated in many cases, since it has the characteristics of a high-pass filter, tending to accentuate the harmonic content of the transmitted signal."

I never tried it, but I`d bet that someone has measured the radiated harmonics both with and without the Faraday screens inplace. That would prove effectiveness.

Short-circuiting the open ends of the Faraday screen wires would kill transfer of the signal between primary and secondary of the transformer, and the transmitter would likely complain.

Best regards, Richard Harrison, KB5WZI

4210. measuring antenna resonance with an 8405a

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-06 05:18:33 UTC
From: dansawyeror <dansawyeror@comcast.net>
Message-ID: <3M-dnWU27IqxggjenZ2dnUVZ_sydnZ2d@comcast.com>
Source record: 67007

I would like to know if the follow technique will work to measure resonance of an antenna. I know have a working HP 8405a. It has been a struggle to repair it and to align it, however it now appears to be working.

My plan is to connect a bi-directional coupler to the 8405a. The coupler will be terminated in a 50 Ohm terminator. The phase will be read for this configuration. The next step is to replace the 50 Ohm terminator with a direct connection to an unknown antenna. I will then change the frequency until the phase angle matchs the 50 Ohm phase angle.

Does this make sense?

What are the draw backs?

How close will this method get compared to a noise bridge?

Thanks - Dan kb0qil

I was in the HSC store in Sacramento and discovered some filters that were
inside the AC switch. I decided against them, since I wasn't sure about the
amperage. I would think though the chassis builder might include such
devices, but haven't checked. Tomorrow I'll order the corcom filter 10ek7 10
amps that someone suggested from a place in San Jose, CA. $5.00. I'll give
that a whirl. Looks like I'll have to cut the cord to put it in the line.

Sorry, I meant "Faraday screen", which is the term you used, and I used in my posting explaining its operation.

If you block either the E or H field, you also block the other. You can't independently block one or the other.

> . . .

> Why would one pay a lot of extra money for a transformer which

Because in order to "work" it doesn't need to "eliminate capacitive coupling". All it needs to do is locally reduce the E/H field ratio, which is what it does.

My suggestion would be the following:

Cut that buried 1" pipe about a foot over the ground, to serve as a ground support for your new antenna.

Get a heavier steel pipe (ca 1"3/4 - 2") that will fit over the 1" pipe, and perhaps 10 foot long.

Get a cheap fiberglass (not carbon) fishing rod ca 18 feet long, (1/4 wave on 20m)

Tape a 1/4 wire radiator to the fishing rod, and feed with coax at bottom of rod.

Attach fishing rod securely to the top of your new mast pipe.

Rise the pipe and fishing rod assembly vertically and guy at the point where the fishing rod is attached.

Now you can run elevated wire radials along the guy ropes, and you should probably also ground the coax shield to the mast pipe at the feed point.

Enjoy!

Others on this newsgroup have admonished me for worrying about
energy and refused to discuss the subject. I thought you were
doing the same. Sorry. But do you actually have any references
that contradict "Optics", by Hecht?

In Dr. Best's article, he superposes V1 with V2 such that constructive
interference energy is needed to complete the superposition. On this
newsgroup, I asked Dr. Best where that necessary constructive interference
energy comes from and he didn't know. That's when I went searching for
references and found them in the field of optics.

Constructive interference energy can be supplied by local sources
as occurs in W7EL's "Food for Thought #1" with its DC example. Or
constructive interference energy can be supplied at a point away
from the source(s) by destructive interference, e.g. wave cancellation
at the non-reflection surface of a layer of thin-film on glass or
at a match point in a transmission line.

Ya, I see they drop their signal strength from 50kw to 10kw at night. What
would be the best antenna design for this station. I've considered buying a
tuned loop for this frequency but I'm reluctant to drop $70 and maybe not do
any better than my straightwire.

Dan, the phase angle of the reflection coefficient of a matched load is unimportant, and is likely to be anything. Specifically; if it is a dot on the Smith Chart center -- who cares? Typically the return loss of a good quality load could well be > 40dB. Again, if you are measuring beyond the frequency range of the coupler you must determine its directivity. It is very likely that you are reading the phase of poor directivity and not the 50 ohm load. Also if you are using the 8405A, do you have all the accessories? In particular the BNC (+ 50 ohm thru) probe attachments which should be connected directly to your coupler ports. If you require N - BNC adapters to connect to the coupler, then as long as you have the same structures on each port, any phase error will be cancelled out. It is also good practice to attach a high quality 20 dB pad to the input of the coupler (thus ensuring your source return loss approaches 40 dB) -- you cannot always be certain that your source, plus coax, provides a good match. Note if the unit cannot lock with the 20 dB pad, then at least use a 10 dB pad.

Another test is to connect both probes to the same source via a BNC "T" adapter. Do you show zero phase error?

Interesting you have an 8405A, it is many years since I used one. I see them priced from $250.00 to a fully refurbished unit from Tucker (www.tucker.com) for $2,500.00.

Regards,

Frank

If you're really going to feed the antenna with coax, why do you need
a balun? Just run the coax straight to your tuner coax connection.

You're losses on various bands may be pretty high with coax. That's
why most all-banders are fed with ladderline. Losses are lower. But
that's your choice.

Didn't you say you had an unbalanced tuner? Most modern ones have a balun to perform that function. I suspect there is one in there. I have been toying with an "old school unbalanced one that uses a couple roller inductors, but I haven't seen too many of those around.

At any rate, if you put up 140 feet of dipole, and want to work 160-10 meters, you *should* be using balanced line, and a tuner that can handle that.

Trying to use a coax fed system and tuner in this manner, you'll not have very good luck. The coax will have problems at some of the very high mismatches at some frequencies.

>Does this make sense?

Sort of, but not exactly. As I described in another thread, the
pitfall is the fact that the phase lengths of the coupler are
different. You could set the phase offset to zero at frequency X but
when you change to frequency Y, there is a built-in error.

The correction for this is to use a line stretcher that (more-or-less)
equalizes the phase lengths with respect to frequency.

>
>What are the draw backs?

See above.
>
>How close will this method get compared to a noise bridge?

With a little care you can make measurements that leave noise bridge
measurements in the dust... not even close. With -lots- of care, you
can approach network analyzer accuracy... more than is needed for
practical antenna measurements.

You need to see H-P App note AN77-3. When I get time---and with my
dial-up connection---I mean lots of time, I will try to post a 13
MByte .pdf on qsl.net, if that's working.

I should have added that you don't do this with a 50 ohm load, but a
short circuit instead. You want a big reflection with a known phase
for a calibration standard.

After reading this thread it seems there is significant confusion between E and H fields created locally from electric current and the E and H aspects of a passing RF photon stream. It is easy to see how this can occur. That said the tools for working with them are entirely different.

E and H fields from capacitors, inductors, and transformers are predominantly local effects. Photons are not involved, they are created by electric current and are explained by Maxwell equations. They can be created separately, that is a capacitor is pretty much a pure E field and an inductor an H field, albeit none of these are perfect. Photons are not involved in the operation of a

On the other hand EM waves and photons which are RF waves and visible light and beyond are entirely different. Although they are referred to as electro-magnetic, they are in fact massless particles with a well defined energy that is a function of frequency. These particles, traveling at the speed of light, create what is referred to as RF including RF fields. The E and M components cannot be separated. Antennas are devices which convert RF currents into photons for transmission and to convert photons into RF currents on reception, all this at the frequencies we are mostly interested in.

These are two very different physical constructs. Now at RF frequencies - Faraday shields are local electrical devices, they have nothing to do with photons and antennas. (Although they may be effective at blocking their passage.) Electric currents in equipment create both E and H fields. These fields are not associated with photons and can be separated. Faraday shields are a way to block the E portions of those local fields while allowing the passage of the H.

Owen has a feedline loss calculator at: http://www.vk1od.net/tl/tllce.php
EZNEC (including the free demo version at www.eznec.com) can be used
to estimate the SWR to plug into the calculator.

For instance, 100 feet of RG-58a used on 14 MHz with an average SWR of 5:1,
loses ~4.7 dB, or ~66%.

To get the same loss with Wireman #554 ladder-line, the average SWR could
be allowed to equal 53:1.

The first step is to establish the accuracy of the test equipment. A short/open at the output port of the directional coupler should produce a frequency independant phase shift between the forward and reverse coupled port. If you are not getting 180/0 deg, then there is something fundamentally wrong with the test set up. Connecting both probes of the 8405A to the same source should establish if any errors exist in the vector voltmeter. Using the BNC/probe adapters is essential to maintain repeatability in your measurements.

Reference HP's 778D coupler at
http://cp.literature.agilent.com/litweb/pdf/5952-8133.pdf :

"
Impedance Measurements

The 778D is also well suited for measurements of impedance when used with

the Agilent 8405A vector voltmeter. The technique is described in Application

Note 77-3, Measurement of Complex Impedance, available at your nearest

Agilent sales office. Again, a reflectometry technique is used. With the vector

voltmeter, however, both magnitude and phase angle of the reflection coefficient

can be measured. This setup is shown in Figure 3.

Data can be read from the two meters of the vector voltmeter and transferred

directly to a Smith Chart to provide impedance of such devices as antennas or

other passive components.

"It is many years since I have seen AN77-3, but I seem unable to find a copy on the web.

At the risk of starting something... Owen, I didn't see this point in your initial post. I've read a few of your posts and you seem to give pretty good explanations.

I thought the answer would be that a wideband Balun (my assumption that the OP is referring to this type) of the type commonly used (Ferrite core & windings) is not recommended for a multi-band antenna where the impedances vary widely. These baluns, I thought, are suitable only for impedances near their design center. For example, a 1:1 balun works well in a 50-50 ohm, 50-75 ohm or 75-75 or 50-33 ohm system. A 4:1 (or perhaps more correctly 1:4) works ok with 50-200. 50-300, 50-133.

Using a 1:1 between tuner and antenna (at either end of the feed line) when the antenna impedance may be 200 or 1000 ohms on some band, causes grief for the balun in the form of poor efficiency and possibly a burned up balun - because the balun is operating in a system impedance much different than this design center. These baluns are not suitable for a wide range of impedances.

Do I need to change my brand of drink, or have I got a reasonable understanding?

Owen,

It is my understanding that (ignoring patterns and focusing initially on the antenna) using a dipole which is not resonant on one of the harmonically related ham bands (I believe the original Windom-circa 1945 and G5RV are in this category) avoids the problem of matching to the very high impedance at the even overtones (a 40M dipole is two half waves on 20M and a high Z). Yes, using ladder line vs. coax helps with this greatly, but then you have this age old problem of the bal to unbal issue.

This, of course, somewhat ignores feed line loss, but this is a first approximation focusing on the antenna initially - and I realize that ignoring feed line loss is not what you do when looking at the WHOLE system.

. I'll have to read your referenced article more fully (next). (:-)

73, Steve, K,9.D;C'I

P.S. For the beginners, A signal has a harmonic. A resonant object (antenna, crystal, resonator, filter, etc) has an overtone - which is a resonance, typically but not necessarily, harmonically related - frequently slightly off the harmonic due to strays.

It might be useful to also point out the means by which these electric and/or magnetic shields do their job. They do it not so much by blocking as much as by diverting the fields. They serve to conduct the field around the object that is being shielded.

Sometimes an antenna needs matched to the coax line. An extreme example is an OCF dipole, which can operate on several bands, but has an impedence of several hundred ohms. the 4:1 or 6:1 balun will match that with the 50 ohm coax.

Maybe I misunderstand, but what you seem to be saying is that if I put
Probe A at point X on a transmission line and Probe B at point X+Y
(Y>0), the phase difference with respect to frequency will not change.

The directional coupler is no different, it is sampling the main line
at two physically different locations.

Cecil,

I do not have a copy of Hecht, but I doubt that he has made any serious mistakes. Certainly he should have no mistakes in an area that is as well understand and widely discussed as plane wave interactions with discontinuities in the medium.

The classic treatment of this problem, found in virtually every college-level textbook on E&M or optics, is to set up the appropriate wave equations, add the boundary conditions, and crank out the answer.

Then there is typically some sort of analysis and discussion that says, "The reflected intensity plus the transmitted intensity is equal to the incident intensity. Energy is conserved." I suspect Hecht provides exactly that sort of description. I know that all of the relevant textbooks I have do so.

I believe you are reading too much into something Hecht is saying, perhaps in an effort to somehow reconcile conservation of energy.

The beauty of the laws of E&M, as expressed by Maxwell's equations and other fundamental properties, is that conservation of energy is automatic, at least in ordinary circumstances. If one correctly solves for the field equations, the energy conservation will come along for free.

Conversely, it is customary to use energy considerations as the primary vehicle for addressing many physical problems in advanced mechanics, quantum mechanics, solid state physics, and other branches of science.

The bottom line is that there are a number of tools available to develop correct solutions to physical problems. Steve Best chose one path, and you choose another. You both come up with the same answer in terms of what can be measured. The mathematical constructs underlying the solution may be different, but those constructs are not directly measurable.

Don't limit your toolbox. Sometimes a screwdriver is easier to use than a monkey wrench.

The answer was in the graphs in the referenced article. If a reader would be satisfied by a simple answer, the answer is no, it isn't practical. But if they wanted to know why it wasn't practical, the information and a better solution were both in that article which was generally about the issue of whether the traditional wisdom of a dipole, one half wave long at the lowest operating frequency, fed with coax and "loaded up" with an ATU would be a good multiband antenna.

Steve, it is certainly a challenge to implement a balun that works over the range of impedances that would be encountered in a 140' dipole from 1.8 to 30 MHz.

To my mind, the very high coax loss dismisses the solution before you visit the balun problem.

Without detailed analysis, my guess is that the 140' dipole will be far enough off resonance to cause high coax loss on 80m, there is the slimmest chance that it would fall into 30m as a 3 x 1/2 waves, and it is unlikely to have low coax loss on any other band. Hence my statement that it is unlikely to have acceptable coax loss on any band, save possibly one.

Ok, that is where the answer to the question about coax feed to a multi band dipole lays. The two graphs show (1, 1a) show in an instant that the problem is in the feedline, and other graphs show feedline solutions that are better.

Nevertheless, the balun problem remains if you have an unbalanced ATU.

I think the balun design can't be adequately addressed by considering just passive component between an unbalanced generator and balanced / floating load. A more complete answer is found by modelling the entire system (inc real balun and feedline) as part of the antenna system in NEC. The unbalanced shunt L and the value of the series R and L introduced by real baluns will have different effects depending on the length of the feeder, where it is earthed, how it is coupled to the nominal radiator etc. This approach is interesting in considering whether the balun should be on the tx or ant side of the ATU.

I ran a range of models following my G5RV article at http://www.vk1od.net/G5RV/index.htm exploring baluns in that context, and finding a solution that reduces common mode feedline current significantly is challenging. The closest I came was a W2DU style choke balun that was four times (or more) the traditional lengths, and would reduce common mode feeline current to less than 10% of the nominal radiator current. It is a work in progress!

I lament the unavailability of quality commercial ATUs that deliver uncompromised balanced output. (Yes, I know MFJ have recently released a product, but I did say "quality").

With respect, I think you two guys are talking about different kinds
of couplers.

Wes, your earlier description makes is clear that samples in the
coupler you described are located at equidistant from their nearest
ends, but not in the centre, so at different positions in the coupler.
I think the coupled lines type of coupler for lower frequency use
might fit this category.

Frank assumes a coupler where the samples for both ports are taken at
the same physical location on the main line. I think a crossed
waveguide coupler might fit this category (depending on the way the
coupling holes are implemented).

> exactly that sort of description.

Much more than that. As you know, irradiance is power/unit-area
and Hecht spends many pages on irradiance and energy.

> I believe you are reading too much into something Hecht is saying,
> perhaps in an effort to somehow reconcile conservation of energy.

Spoken by someone who hasn't even read Hecht? I suspect if you
read Hecht, you would perceive the same information as I. Hecht
is big on conservation of energy and spends many pages discussing
such things involving EM waves.

> The beauty of the laws of E&M, as expressed by Maxwell's equations and
> other fundamental properties, is that conservation of energy is
> automatic, at least in ordinary circumstances.

There is still an underlying Q&A about what happens to the energy
in those waves. The energy concept is in addition to what's already
there, not any kind of replacement for it.

> The bottom line is that there are a number of tools available to develop
> correct solutions to physical problems. Steve Best chose one path, and
> you choose another.

Nope, we chose the same path. Steve just fell off the path and
down the cliff about 2/3 of the way through his articles. Steve
gave us a very good picture of what happens to the energy toward
the load but he gave us a distorted view of what happens to the
energy toward the source. Instead of Steve's one-sided approach,
I presented both sides thus merely expanding what Steve had
already done.

> Don't limit your toolbox.

Funny, just above you seemed to recommend limiting the toolbox
to Maxwell's equations and tried to discourage me from thinking
about energy.

Cecil,

The waves you are so worried about are merely convenient, but
fictitious, adjuncts to your mathematical model.

You need worry only about the energy of real, measurable waves, not
those adjuncts that simplify the math.

The use of such adjuncts is done frequently in solving real problems.
Just don't confuse the internals of the model with physical reality.

4247. Antennas And Lightning Induced Voltage Transients

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-06 20:08:43 UTC
From: Robert11 <rgsros@notme.com>
Message-ID: <po2dnQQrb_pbcgjenZ2dnUVZ_tydnZ2d@comcast.com>
Source record: 66944

Hello:

We get a lot of lightning strikes around here, and was wondering about this:

Presently have a receive-only random length wire running around the inside
of my attic.

Guess I'm not really too worried about "direct" lightning strikes; if there
is one I imagine I have a lot more to worry about than the radio.

But, does the roof provide any protection from nearby lightning strikes
inducing a high transient voltage
into the indoor attic antenna wire, as compared to if I had the wire antenna
strung outside the house ?
Again, from an induced voltage standpoint concern.

Or, is the fact that it is indoors really meaningless ?

Thanks,
Bob

Gene Fuller wrote:
> The waves you are so worried about are merely convenient, but
> fictitious, adjuncts to your mathematical model.

Let's see:
1. Canceled waves are "fictitious adjuncts to my math model".
2. Therefore, they don't need to be canceled, because they
are only "fictitious adjuncts to my math model".
3. Therefore, we can remove whatever is doing the canceling
of those "fictitious adjuncts" without changing anything.
4. Darn, how is it that I can see those "fictitious adjuncts
to my math model" so well that I can't see anything else?

What's wrong with this picture? Could there be a not-so-hidden
contradiction accompanied by confusion of cause and effect?

> You need worry only about the energy of real, measurable waves, not
> those adjuncts that simplify the math.

You don't even know me, Gene. Where do you get the balls to
decide what I need to worry about and what I don't need to
worry about? I have been worried and needing an energy analysis
model for 40 years. I now have one and can now sleep like a baby
at night, but no thanks to you. :-)

I think the reason why you don't see rabbit ears oriented horizontally
is that they don't seem to work well as dipoles. When standing up they
aren't even a V antenna and at first one would think they are
vertically polarized but they are somewhat directive with a bipolar
pattern. Rabbit ears are a bastardized form of a couple antenna types.

Sometimes mainly one element is responsible for most of the signal
while the other behaves as a reference or ground. For example on low
frequency channels like Ch-3, reception is best if one of the elements
is oriented straight up and the other horizontally pointing in the
direction of the transmitter. This won't work well with Ch-12 and the
standing V is best then.

Jim Kelley wrote:
> "100% wave cancellation means 100% energy reflection."

That's a no-brainer when quoted in the context of an
RF transmission line. Shame on you for once again quoting
something out of context. If it happened in space, it
would say, "100% wave cancellation means 100% energy
redistribution." as explained on the web pages below.

There are only two directions in a transmission line. If
energy rejected by a mismatched load doesn't make it to
the source, in a lossless system, it must necessarily
be 100% re-reflected. Rho^2 is reflected by the impedance
discontinuity at the match point. That's step one. Step
two is that 100% wave cancellation. Given those two steps,
no reflected energy flows toward the source. Therefore,
it must necessarily have been re-reflected back toward the
load. Since it joins the forward energy wave, we can
measure that is exactly what happens. It's a no-brainer.

Here's the in-context quote.

The destructive interference energy resulting from wave
cancellation at an impedance discontinuity becomes an equal
magnitude of constructive interference in the opposite
direction. Since there are only two directions in a transmission
line, wave cancellation is the equivalent of an energy reflection.
100% wave cancellation means 100% energy reflection. [9]

[9] Quotes from two web pages from the field of optical engineering:

www.mellesgriot.com/products/optics/oc_2_1.htm

"Clearly, if the wavelength of the incident light and the thickness
of the film are such that a phase difference exists between reflections
of p, then reflected wavefronts interfere destructively, and overall
reflected intensity is a minimum. If the two reflections are of equal
amplitude, then this amplitude (and hence intensity) minimum will be
zero."

"In the absence of absorption or scatter, the principle of conservation
of energy indicates all ï¿½lostï¿½ reflected intensity will appear as
enhanced intensity in the transmitted beam. The sum of the reflected and
transmitted beam intensities is always equal to the incident intensity.
This important fact has been confirmed experimentally."

http://micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index.html

"... when two waves of equal amplitude and wavelength that are 180-degrees ... out of phase with each other meet, they are not actually annihilated, ... All of the photon energy present in these waves must somehow be recovered or redistributed in a new direction, according to the law of energy conservation ... Instead, upon meeting, the photons are redistributed to regions that permit constructive interference, so the effect should be considered as a redistribution of light waves and photon energy rather than the spontaneous construction or destruction of light."

Note from W5DXP: In an RF transmission line, since there are only two possible directions, the only "regions that permit constructive interference" at an impedance discontinuity is the opposite direction from the direction of destructive interference.

May be, but his link:

http://cp.literature.agilent.com/litweb/pdf/5952-8133.pdf

shows exactly what I'm talking about in Figure 3. Note the line
stretcher on one sample port. Because I haven't seen the inside of one
of these I don't know where the coupled arms reside with respect to
each other but the fact that H-P shows the line stretcher tells me
that they must have some (unavoidable, if not purposeful) asymmetry.
They claim 4 degree phase tracking but it's unclear to me whether they
mean the coupled arms with respect to the main line or to each other.

The type of coupler I am thinking of is indeed where the coupling lines for forward and reflected are in the same physical region. The point I was making refers particularly to the HP 778D; where it is specified in:
http://cp.literature.agilent.com/litweb/pdf/5952-8133.pdf
"Data can be read from the two meters of the vector voltmeter and transferred directly to a Smith Chart". Indicating that there is no significant phase error over the nominal bandwidth of the coupler. It is certainly something I have always taken for granted, but in recent years have been spoiled by Agilent's VNAs. Even Matthaei, Young, and Jones' classic text does not get into specifics of the phase response of TEM couplers. If I get a chance in the near future, I will run a phase response of an HP778D coupler, and/or also run an Eagleware simulation of a co-planar WG coupler.

Just read Wes' comments on the line stretcher on the above pdf. I must admit I also wondered about that, but assume it is intended as a cal

adjustment for a short/open standard. Even VNAs, in their non calibrated state, show a pretty good dot on the right/left of the Smith Chart for an open/short in the lower hundreds of MHz.

Incidentally I have tried to access the http://www.qsl.net/n7ws/Pages%20from%20AN77-3.pdf which is unbelievably slow, but I keep getting error messages saying the file is corrupted. I am using a 2.5 Mb ADSL, which is normally pretty fast.

4255. Problem with dual band antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-06 22:18:56 UTC
From: Ed Laughery <laughery@bellsouth.net>
Message-ID: <Y4olf.227$wP3.28@bignews6.bellsouth.net>
Source record: 66952

Hi

I installed a NOS dual band (2m/70cm) thru glass antenna on my Toyota Highlander today. This a Radio Shack antenna that was carried in the stores about two years ago.

I made sure to mount on glass away from defroster lines, no metal film sun screen, and away from major metal. Using my MFJ analyzer, the best SWR on two meters is 5.9 - 6.1, SWR on 70 cm is a 2.0 - 2.2. The interior interface block has a trimmer cap that is working - SWR is affected but will not improve beyond the cited numbers..

I tried sweeping thru a board range of frequencies in the 2 meter band and cannot find a resonant hotspot.

The RS package indicates that the antenna should be 2.0 or less thru the bands with a VSWR around 1.1 at 146.00 and 445.00 MHz.

Any ideas what may be the problem and/or what I might check.

BTW: I checked other antennas with the same analyzer and they read correctly.

Thanks in advance for your consideration.

Ed

In the olden days that antenna required a stub inside your vehicle.
Memory may fail me but if I recall correctly it was about 7 inches long
and attached to the window coupling inside the vehicle.

Do you have such a setup?

I have done this type of measurement and the coupler is somewhat
un-important in regard to where on the line its samples are taken from. The
line stretcher does the compensation to place both samples at the same
point on the main line. It is set in a calibration process to get to that
point (seems to mee only a short is required). Memory is starting to fade
here, but if you want the samples to be "at the plane of the DUT" then you
either must use two line stretchers or use the vector voltmeter capability
to compensate for the difference in sample location vs. DUT location. If I
recall correctly, this is simply a phase offset and the old HP vector
voltmeter has such an offset capability.

Look at it this way. You want the FWD and REF phases to be at the DUT. To
do this you must put an equal (electrical) length of line in all three
sections of line - the desired, the FWD sample and the reverse sample. I

admit the reflected part has an intuitive glitch that I can't resolve at this time since it is always longer, but I know this works. You can sweep the set-up and the phase of the two samples will sit right there on that of a short . This rells you that the samples are "at the DUT".

Right??

I could be wrong, but I think that 4 deg seems part of the tolerance
of the phase alignment of the two sample ports wrt each other over the
frequency range. Perhaps this is a coupler where the ports are
approximately in phase, and perhaps the line strether is to adjust
phase of forward and reflected ports to create a new reference plane
where it is needed or convenient to the measurement.

I don't think you were telling us that the battery went flat at that
moment, so...

Don't you have digital television? Best thing since sliced bread.

I don't know if you can receive analog television beyond the digital
coverage ranges, but you probably wouldn't want to watch it.

Digital TV makes weak signals most watchable, DVD quality at weak
signals.

I use it and I am only 4km from the transmitter, but that is another
situation where it works a treat, ghost free pictures close to the
tranmitter in the presence of local reflections (hills, water towers
etc).

The old vector voltmeter has a phase offset ability to compensate.

See my previous post on this. It IS used to get both samples "At the
measurement plane."

The roof has absolutely no significant magnetic properties, right? SO...
the high current of the lightning is the "primary" of a transformer. The
wire in your attic is the "secondary" of a transformer. A pretty poor
transformer, but with that current, it'll induce lots'a voltage in your
wire...roof or no roof. Right?

The roof protects the antenna from lightning, even the sneaky stuff.
All you have to worry about is lightning striking the roof and
yourself if you are not under it.

Well, I did change something, as I finally recall now (as prompted by M. Coso's post). I did put a new (used) monitor on that computer about 10-14 days ago. Maybe it had some affect. Dunno. I guess I could always try the original one. Tomorrow.

Hi,

Given the circumstances you have.. I would give some thought about putting up a vertically mounted Small Transmitting loop such as the MFJ. Will it work as good as a Vertical? , not one that has a good radial system under it and a clear shout at the horizon.. but it sounds to me like it might be just right for your needs.. Give them a Look I built one here and used it for a couple of years mounted only 3 feet above ground and it worked surpizingly well , considering it's size about 3' in diamiter . If I were in your situation I'd mount it about 1 or 2 feet above the trailer roof.
Hope this helps,
73 DAVE KC1DI

If they specify a physical length (24"), and nothing else will do, then the type of coax is absolutely critical as its velocity factor will determine the electrical length.

However I suspect the bridge output is not at signal frequency but DC so the cables will not be critical. It is very difficult to see how they could make it work to 4GHz with several wavelengths of coax in the signal path, acting as an impedance transformer. Two feet is a significant length even at HF, and will shift the phases considerably.

Ok, Steve, makes sense. Anyway, have re-visited Matthaei et al, and also "Foundations for Microstrip Circuit Design", by T. C. Edwards (Edwards does appear to contain an error referring to "j-omega", which should simply be "omega"). Both texts agree on the expression for coupling on a single section, quarter wave, TEM mode, coupled transmission line. Also realized that the equation does contain a frequency parameter.

Running an analysis in MathCAD, for a 20 dB coupler with design center at 150 MHz, produces some interesting results:

Coupling at 100 MHz, and 200 MHz = -22.5 dB;

Maximum phase error -- at band edges = +/- 2.5 degrees.

Increasing the frequency range of analysis from 50 to 250 MHz shows a dramatic drop in coupling amplitude, at these frequency limits, to 32 dB. Phase error, however, does not seem to be effected very much; peaking at +/- 2.8 degrees, and following what appears to be a sinusoidal curve.

From experience I know that coupler directivity degrades significantly beyond the design bandwidth. Edwards does state: " Values of directivity, on microstrip, beyond 12 to 14 dB are difficult to achieve". Co-planar structures are much better, and can easily be analyzed with Genesys' 2.5D EM simulations. Without access to HFSS, or similar FEM programs, I doubt directivity could be calculated for coaxial structures.

The main problem, with operation of a coupler beyond its design bandwidth, appears to be its loss of coupling. This, combined with degradation of directivity, would certainly account for very large phase errors.

Frank

Up comes the RF noise floor.... The big problem that affects any AR operation in urban areas...

I have a dirty insulator somewhere nearby. Rain helps a lot! It is however a much greater source of noisie than the PC - so I dont need to fix the PC yet..

<grin>

For sure not VHF. They may be expensive now with HD TV, but in my day they
were cheap UHF TV antennas in Michigan, my home state.

I tend to agree, but as someone who used to write specs and then sit
back and watch vendors try to skirt them, I'm always dubious. :-)

>Perhaps this is a coupler where the ports are
>approximately in phase, and perhaps the line strether is to adjust
>phase of forward and reflected ports to create a new reference plane
>where it is needed or convenient to the measurement.

I think what's being missed in this discussion is this: The 8405 has
a phase offset adjustment that can make -any- relative phase read 180
degrees on the meter. So you could put a short on 100 feet (30.48m)
and adjust the phase offset to make the meter read 180 deg. This
would be fine until you changed frequency then you're in trouble.
That same effect is the reason for adding a line stretcher; it's to
make that 180 degree relationship track with respect to frequency.

Paragraph 2 of the document I provided explains this nicely.

I've built reflectometers (many times) where dual couplers were not
available and two back-to-back singles were used. (Sometimes, three
were used with the added one in a feedback loop used to improve the
source match of the generator) I can guarantee you that the two
coupled arms didn't phase track and that is the general case that I
was trying to put forth at the outset of this discussion.

4287. Principles of operation for dual band vertical antenna (2m/70cm)

Hi

Am I correct that in a dual band mobile antenna for 2M/70 cm - the lower portion of the antenna is cut for 70 CM and the entire antenna including the coiled portion is used for two meters? Does all or a portion of the coil add to the length for either frequency?

Thanks for your help.

For mine, the coil acts as a loading coil on 2m and a phasing coil on 70cm.

It depends on which section you use. The sections are numbered by the
number of inches one each leg of the triangle. My base is 22 inches and
a 50 ft. tower. Let me know and I will measure. Excellent tower.

There are several types, so you need to give a better description of the one
you refer to.
The "Hershey kiss" one I have looks like a 2M 1/4 wave, but with a small,
3-4 turn coil at the base. It appears to be "5/8" on 440 and "1/4" wave
on 2. However, on 440 the 5/8 needs some series inductance to tune out the
capacitance of the 5/8. With this inductance in there, the 2M 1/4 wave has
un needed loading, so it has to be shortened for a better match. It all
fits. The frequency ratio is ~~ 3:4 and 5/8 is less that 3/4, so it is
shorter than both 1/4 and 3/4... Better get out the yard stick again and
verify my recollection...

I think the Larsen operates as a loaded 2 meter, 1/2 wavelength
equivalent, and as a 2 elrment collinear on 440.

Quite possibly there is some sort of grounding issue. I only bring up the monitor possibility because I have seen the way some monitors, and the circuitry that runs them, can really sing when a change is made. What adds spice to the problem is how Windoze will sometimes change resolutions on ya. Happens a lot more in DOS, but if a person is a gamer - or a Ham who still uses DOS - it can come into play more often than we might think.

My interest is piqued! Mr Watson - don't you dare solve this problem and not let us know what the cause was!!!! 8^)

Wes,

Thank you. Two couplers configured "in to in" from a tee, to set up isolated "in phase" coupler signals, do seem to maintain very close to a relationship across frequencies. This was observed with an oscilloscope

After much scrounging around to make the connectors a constant length and number the 8405a does not maintain a constant phase across the same inputs. The 20kc IF output shows a significant phase change across the same frequency range.

Its back to the drawing board to re-tune the 8405a. Somewhere in the process I missed something. The phase angle should not vary that much.

Dan

>I have no trees, streelamps, telephone poles, or anything higher than a
7 foot trailer. That was why I was considering a vertical. For
practical purposes anything higher than 40 feet is forbidden and 25
>foot is as high as I practically dare do.

You could use a mobile antenna on the trailer and have a decent
signal.

> From what I understand,
dipoles are not effective below 1/2 wavelength above the dirt, but
verticals can work well fairly close to the dirt if they have to. From
what I hear inverted vees are slightly better than dipoles but slightly
>worse than verticals at low altitude.

It all depends where you are talking. For NVIS, even a low antenna
will do ok. I've run quite a few low dipoles in portable use, and
never
had any problems. 1/2 wave up? If that were true, my dipoles here
at the house would be no good. They are only at 40 ft. Thats barely
more than a 1/4 wave up on 40m. 1/8 wave on 80m... I have no
trouble at all, and that includes dx. I can work dx on 80m with only
100w no problem.
In general, dipoles are better than inv vees at any altitude. At low
heights, you have less ground losses, and the antenna is higher
above ground in general. But, thats not to say an inv vee won't work
ok. It will. A flat dipole is best though, if perfection is desired.
Slightly less than low verticals? Who can say. It could be much
worse, or much better, depending on the quality of the vertical,
the band and path used, etc...In general when camping, I'd
rather run a low dipole, than a ground mount vertical with few
radials. Any vertical not ground mounted, I consider a ground plane,
and it must have resonant radials. Again, it could be better, worse,
or about the same... :/ Depends on band, path, etc.. The low dipole
would smoke the vertical on NVIS on 40/80, but the vertical
might win to long haul dx late at night if it's any good.

>My wife really doesn't care about money as much as she cares about
waste. If I can make my setup working with the stuff I already bought
then great... At this point I am considering just throwing in the towel
and raising a 20 foot iron pipe to mount a 20 meter inverted vee...
>sigh.

Probably what you should have done in the first place...:/ Would
work better than most anything else you will likely try. I would
have made my usual fanned paralleled dipoles fed with a single
coax if I could squeeze the room, and had a place to tie the ends

off. Sounds like you don't really....

>20m is my favorite band, followed by 40 then 30.

Why not use the "no radial" verticals? IE: cushcraft R7, and others
of it's ilk? Those are good for what you are trying to do...
And they will usually work better than a vertical that needs
radials, but doesn't have all it needs due to a limited location.
Yes, you can use helical radials, radiator, but don't it expect it
to be a world beater. A simple dipole would probably eat it for lunch
and be cheaper and easier to build. I've used quicky dipoles portable,

no higher than my own height, and had no trouble talking. And that
was mainly on 75 and 40. One time I did that only running a yeasu
ft-7 with 10w output, and had no trouble. That was at Lake Amistad,
out in the psuedo desert. Not many trees where we were. I found a
tall 6-8 ft stick, and use that to support the dipole. The ends were
tied off to low bushes, or whatever.. Even with 10w, I was averaging
S9 or so to most people around the state. Not too bad. Would
have been 10-20 over 9 with 100w probably.

Meaningless. A neon to ground is traditional for
receiving antennas. Makes a good EMP indicator.

Tuner-balun-ladder-antenna is better. Lower losses if
the tuner is doing anything, i.e. antenna is not 50+j0 ohms.

Source record: 66898

Hi

The antenna that I am working with is built as follows:

The base to coil section is approx 7 " - depending on where I am measuring, this would pretty much coincide with a 1/4 wave 440 segment - next is about 12 turns (.5 "" dia.) followed by a 17 " segment. I cannot reconcile the length for two meters. With an analyzer, I cannot sweep thru freq. and find any close resonant point at 2 meters. This is a thru glass antenna but regardless of direct coupling or putting between glass, I can only get a VSWR of 1.9 - 2.1 on 440 and 6.+ on two meters. I certainly don't mind trimming the top section, if I have a chance at making it work as the dual bander it is supposed to be. Any bit of wisdom would be greatly appreciated.

Thanks for the quick response i have however a few more questions.

This is for notching disturbing tv channels on my tv areal and there are
several that I want to notch.
Lets asume that I only want one Notch pr TV channel is it then possible to
connect several notches on the same spot without the 1/4 wave??? If yes is
there a limit.
I have looked at some commercial filters and they use 2 notch at the same
spot and then two more 1/4 wave apart but the are tuned to the same
frequency as the first pair.

If a symmetrical response is OK, separate the 2 notches by a 1/4 electrical
wavelength.
Typical 3dB BW on our small UHF symmetrical notches is +/- 1.2%

Anon wrote:
"What are the functions of each of these?"

My dictionary says:
"Diplexer - "A coupling unit which allows more than one transmitter to operate together on one antenna."

The first AM broadcast plant I worked in did this with stations on 950 KHz and 1320 KHz. It was faultless.

Duplexer - "A radar device which, by using the transmitted pulse, automatically switches the antenna from receive to transmit at the proper timwee"

I`ve seen gas tubes used for this in radar sets in the navy and company owned boats I worked on. Again, it worked like a charm.

Combiner - "A circuit for mixing video, trigger, and scan data from the synchronizer for the modulation of the link."

Obviously definitions depend on applications. For example, I`m familiar with combiners used to select the best signal from multiples in diversity reception.

Hi
Well, not exactly, but close. A half wave on 160 is 260 feet, half of that is not 140 as in the Cobra and 80 meters half wave is about 134 feet, so half of that is not 70 feet, as in the Cobra antenna. But its a good enough starting point to work with I suppose. Maybe I'll try 35 feet for 40 meters.
Thanks

Jeff Dieterlle wrote:
"I ran RG 6-U coax to the roof of the factory (approx. 100 ft) and considered buying a loop antenna but at this group`s suggestion connected the coax to the long wire. The stations I`m interested in are Indianapolis 1070 kc and Chicago 670 kc & 1000 kc. I installed 200 ft of #12 ga insulated wire that is oriented in line with these 2 cities and....."

Jeff didn`t say how far he is from the stations. All 3 stations run 50 KW but have daytime directional patterns which may affect the signal strength he receives.

50 KW nondirectional can produce 1860 millivolts per meter at one mile or 9.3 millivolts at 200 miles. I said may because it depends on ground conductiviyty and other factors. I listen to to a 50 KW station 200 miles away 24 hours.

RG-6 has a capacitnance of 20.5pF/ft. So, 100 ft. totals 2050 pF. At 1000 KHz, its reactance is about 78 ohms. This is shunting the impedance of 61 meters of 12 gauge wire (0.0033 WL), a fairly figh capacitive reactance at 1000 KHz. This is a voltage divider. Most of the energy captured by the wire is dropped scross the wire and reradiated never reaching the receiver. That was why a loop which matched the coax was suggested.. Jeff pribably gets enough signal in his antenna. He might get more of it to his receiver using a broadband transformer between his antenna and coax which stepped doown the impedance to match the coax approximately. He may need to step it back up at the receiver end. I recall using this arrangement in 1938 with a General Electric all-band doublet kit and it worked well.

Pointing the wire at the station is fine for a Beverage antenna but about 2 wavelengths is needed for a Beverage.. That wold be 1968 feet at 1000 KHz. The Beverage is vertically polarized, as needed to receive a ground wave. Otherwise, shorter antennas may do better at a more broadside attitude towards the signal wavefront. A random wire generally uses its vertical component to receive groundwaves.

Best regards, Richard Harriison, KB5WZI

I didn't say anything about wavelength. The 140 ft. Cobra is alleged
to work on 160m. The 70 ft. Cobra is alleged to work on 80m. So a
35 ft. Cobra would be alleged to work on 40m.

Incidentally, I just modeled a 124 ft. Cobra version that has
performance on 160m that is superior to the 140 ft. version
because the SWR on the 450 ohm feedline drops from about 63:1
to about 47:1 according to EZNEC. Performance is comparable to
a 124 ft. dipole on all HF bands. This looks like a fairly
reasonable way to obtain 160m performance from a 124 ft. antenna.

A word of caution about scaling of this antenna. Assuming that
the 70 ft. version does work on all HF bands, 80m scales to
40m, 40m scales to 20m, 30m scales to 15m, and 20m scales
to 10m. As you can see, scaling from an 80m version to a 40m
version doesn't necessarily cover the WARC bands.

Irv & Jin-

Also consider making a "patch" antenna using the circuit board ground plane. Of course the size will depend on operating frequency, and it will probably not be as good as a ground plane antenna.

I don't have any references, but a web search should find information on patch antennas used on UHF and higher frequencies.

4321. Back to fundamentals

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-08 21:44:07 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <dna9f7$6k5$1@nwrdmz01.dmz.ncs.ea.ibs-infra.bt.com>
Source record: 66918

I have been informed my GRNDWAV3 program is in error - it calculates the power input to a matched receiver to be 6dB greater than it ought to be, or exactly 4 times the correct power input.

Most of my programs calculate results based on what I consider to be fundamental reasoning. But GRNDWAV3 is one of the few where I have adapted formulae from the text books or 'bibles'.

My informant is an Icelandic amateur who appears to know what he is talking about and is mathematically very convincing. For various resons, for the time being I propose to leave him out of this discussion. That is, of course, if a discussion should evolve.

The problem fundamentally revolves around the gain of short vertical antennas, both transmitting and receiving, above a perfect ground, relative to isotropic. But for present purposes what an isotrope actually is can be forgotten about. It exists only in one's imagination.

Numbers cannot be avoided. So let's keep them as simple as possible by starting with the MF standard of 1 Kilowatt, radiated from a short vertical antenna above a perfect ground. Actual antenna height and frequency don't matter.

According to the text books, the field strength from 1 Kw at 1 kilometre = 300 millivolts, which (according to the text books) is correctly calculated by my program.

To calculate matched reciever input power from field strength it is necessary to state vertical antenna height, frequency and radiation resistance. Again choosing simple values -

Antenna height = 1 metre.
Frequency = 20 MHz.
Calculated radiation resistance = 1.758 ohms.
Matched receiver input resistance is also 1.758 ohms.

According to requirements antenna height is short compared with a wavelength. I am confident that radiation resistance is correct at 20 MHz for a 1 metre vertical.

Antenna reactance is tuned out and disappears from the argument.

So we have a simple circuit consisting of a generator with a resistive load of the same value, both equal to 1.758 ohms.

According to the text books (as confirmed by Roy) the generator voltage is 300 millivolts. (A 1 metre high antenna with a field

strength of 300 mV per metre.)

The power available to the receiver is therefore -

Pr = Square(0.3/2) divided by 1.758 = 12.8 milliwatts.

Which is the value calculated by my program although it does it in a different way by not involving field strength. It calculates it more directly from the 1 kW transmitter power and the antenna gains of a pair of vertical Tx and Rx antennas relative to isotropic.

Nevertheless, I think my informant may be correct. That indeed my program states receiver power input to be 4 times greater than what it actually is. IMPORTANTLY, he says an NEC numerical program confirms his own calculations.

NEC programs are not dependent on what a program user's ideas may be about antenna gains relative to isotropic. They calculate directly from fundamental metre-amps and volts.

I am presently out of touch with my informant. I do not know which NEC program confirms his calculations.

I have recently asked Roy what is the voltage measured between the bottom end of a 1 metre long vertical antenna and ground when the field strength is 1 volt per metre. He says it is 1 volt and no doubt the Bibles agree.

It is intriging, if the value should be only 0.5 volts then my program would give the (suspected) correct answer to the simple question -

"What is the power input to a matched receiver using a 1 metre vertical antenna, at 20 MHz, at a distance of 1 Km from a 1Kw transmitter also using a short vertical antenna?" Short is less than 1/4-wavelength.

Is it 12.8 milliwatts, or is it 3.2 milliwatts?

Is there an NEC numerical program which will do the job? If there is perhaps somebody could use it.

Most important, do I have to correct the program bug for the sake of 6 dB when the calculating uncertainty at long distances is plus or minus 10 or 15 dB ?

Reg, G4FGQ

Thanks for the replies...I am trying to construct a multiband antenna for a disabled friend who lives in a Townhouse. He has some room up in the attic. I think I could squeez a 35 foot lnear loaded inverted vee up. Its going to be fed with 300 ohm line. If it works, fine, if not, then its butterfly collecting for him instead of Ham Radio. Hey, its worth a try. Some of the reviews I have read are interesting. BTW, DX Engineering sells 2 models of this antenna using 3 conductor power cable and 300 ohm line. Check thier site. They even let you read the manual in PDF.

Reg, G4FGQ wrote:
"He says it is 1 volt and no doubt the bibles agree."

OK. You have an antenna with some radiation resistance and a lossless conjugate match to a load.

1/2 the antenna voltage which equals the volts per meter field strength in your 1-meter wire, is dropped across the radiation resistance and the other 0.5 volt appears across the receiver load. The radiation resistance of the antenna becomes the Thevenin equivalent source resistance of the generator feeding the receiver load..

The power lost to reradiation is 0.5 volt times the current in the radiation resistance. The power delivered to the matched receiver load is exactly the same.

Best regards, Richard Harrison, KB5WZI

Hi,

I posted here a few years back about my TV antenna:
http://tinyurl.com/a93e9

I'm now thinking of adding a pre-amp as someone suggested.

The antenna rotator receives some power through the walls and roof. Is it possible to use this power to provide power to a pre-amp? If so, does this apply to any particular model(s) of pre-amp?

I'm not using the rotator and would be glad to disconnect it from its power supply if that would simplify matters.

I get good reception on NBC/ABC/CBS (all VHF) in general, but my Dish-811 HDTV receiver only locks onto a sufficient HDTV signal from PBS (UHF), FOX (VHF) and some of the other OTA channels about 75% of the time, and I'd like to do better.

Thanks,

Jonathan

How was your Icelandic amateur doing his NEC calculations? If he
calculated the voltage that would generate 1kW into a load, then excited
his transmit antenna with a matched generator of that source impedance
-- which would drop the power by a factor of four. If he did that and
you did your calculations with 1kW going _to_ the transmit antenna that
would be your source of error.

Don't know what a Cobra is.

But a 124-feet (38 metres) dipole, at a height of 40 feet (12 metres)
in conjunction with 60 feet (18 metres) of 450-ohm ladder line and an
L-match tuner has the following characteristics -

Freq MHZ Loss relative to ideal
1.9 8 dB
3.8 0.5 dB
7.1 0.9 dB
10.1 0.8 dB
14.1 0.6 dB
21.1 0.6 dB
29.0 0.6 dB

Loss includes, antenna, line, tuner and ground.

Data obtained using program DIPOLE3 from website below.

The rotator looks like one of the standard sort, which is powered by a
low-voltage AC signal when it's rotating, and is unpowered when it's
not.

It might be possible to "piggyback" DC onto that arrangement to run
the preamp, but I think it'd be bothersome to try.

A more common approach is to use a mast-mounted preamp which is
designed to have its power fed up the coaxial feedline. You install a
small "DC injector" between the TV set and the feedline, and plug a
wall-wart DC adapter into the injector.

>I get good reception on NBC/ABC/CBS (all VHF) in general, but my
>Dish-811 HDTV receiver only locks onto a sufficient HDTV signal from
>PBS (UHF), FOX (VHF) and some of the other OTA channels about 75% of
>the time, and I'd like to do better.

Preamps are not without their disadvantages. They can do a pretty
good job of helping boost the signal to overcome losses in the coax
feedline and any downstream signal splitters. They don't help at all
with signal-quality problems due to external noise sources, or
multipath reflections due to trees or buildings, both of which will be
amplified just as much as the desired signal. And, if cheaply
designed (and many are!) they can be prone to strong-signal overload
from nearby transmitters.

The antenna you are using looks like a low-to-medium-gain variety,
without all that much directionality... it might not have enough
multipath rejection to keep your signals ghost-free. If it's old, it

may be suffering from enough corrosion on the elements and the log-periodic line to be costing you some signal strength even before the signal gets into the feedline.

Have you checked your coax feedline for quality and health? It's quite possible that the original homeowner installed a relatively inexpensive (and thus relatively high-loss) 75-ohm coax such as RG-59. If the cable's been up for some years, it's possible that its termination fittings (often simple crimp-on F connectors) have worked loose, corroded, or allowed water to seep into the cable dielectric.

You might find it beneficial to replace your whole run of coax feedline with a more modern type - a low-loss RG-6, rated for use with satellite dishes, would be a good choice. Install new F connectors of the appropriate sort, replace the 75-to-300-ohm balun on the antenna, and waterproof all of the connections with Coax Seal or self-amalgamating rubber tape or brush-on "liquid electrical tape" or the like.

It's a linear loaded folding shaped like this for 1/2 of the antenna:

62 feet per side
---------------------------------------+
|
+---------------------------------------+
|
+---------------------------------------FP---> other side

> Freq MHZ Loss relative to ideal
> 1.9 8 dB

The above antenna doesn't have nearly that amount of loss on 160m.

I measured 1.5 inches OD on the 22 inch base. Other sections are too
high to get to to measure and too much snow around to climb. I am not
positive but it sure seemed the legs are narrower on the smaller
sections. You could call Universal to find out for sure.

==========
Tim,

I think the error, if there is one, is most likely at the receiving
end.

The RADIATED power is 1000 watts.
It doesn't matter how it got into the ether from the transmitter.

But you have made me think again about what should be done with
transmitting antenna gain.

Reg.

<g4fgq.regp@ZZZbtinternet.com> wrote:

>The problem fundamentally revolves around the gain of short vertical
>antennas, both transmitting and receiving,

Hi Reggie,

This is not what you proposed the first time through this exercise. As
your original was stated in terms of a field of 1V/M there is no need
to elaborate on about the radiator.

>Numbers cannot be avoided. So let's keep them as simple as possible by
>starting with the MF standard of 1 Kilowatt, radiated from a short
>vertical antenna above a perfect ground. Actual antenna height and
>frequency don't matter.

Then its mention at being both MF (MW?) standard, and being a short
vertical is in distinct conflict. Again, there is nothing inherent to
the problem short of demonstrable evidence in the field, which returns
us to the classic FCC ground wave charts for MF (MW?).
>
>According to the text books, the field strength from 1 Kw at 1
>kilometre = 300 millivolts, which (according to the text books) is
>correctly calculated by my program.

Are you claiming your program computes field V/M or power delivered by
a field of V/M?

>To calculate matched reciever input power from field strength

Here again is a new specification to your original query. Matched? I
would have suspected so, but being unmatched or being mismatched
brings a spectrum of answers that span to more than 1V/M down to
microV/M.

>it is
>necessary to state vertical antenna height, frequency and radiation
>resistance. Again choosing simple values -
>
>Antenna height = 1 metre.
>Frequency = 20 MHz.
>Calculated radiation resistance = 1.758 ohms.
>Matched receiver input resistance is also 1.758 ohms.

Even more elaboration that goes beyond the original. I suppose for
the purposes of discussion it works, but it goes well beyond the

premise of classic MF (MW?) work.

>According to requirements antenna height is short compared with a
>wavelength. I am confident that radiation resistance is correct at 20
>MHz for a 1 metre vertical.

When we have theoretical work supported by real field data in the MW
band, why take up a frequency outside that?

>Antenna reactance is tuned out and disappears from the argument.

This is to be expected, but was never actually expressed anywhere.

>So we have a simple circuit consisting of a generator with a resistive
>load of the same value, both equal to 1.758 ohms.

The generator's Z is immaterial to the discussion if you have a
defined field.

>According to the text books (as confirmed by Roy) the generator
>voltage is 300 millivolts. (A 1 metre high antenna with a field
>strength of 300 mV per metre.)

I have obtained comparable (though not exact) results for real (not
perfect) grounds to compare against actual (not theoretical) data.
Those not comparable have come from mismatched 1M high antennas
against various loads (already discussed above).

>The power available to the receiver is therefore -
>
>Pr = Square(0.3/2) divided by 1.758 = 12.8 milliwatts.

Where'd the 2 of the (0.3/2) come from?

>Which is the value calculated by my program
>
>Nevertheless, I think my informant may be correct.

It is quite simple to fool experts. They are by far easier targets
than the naive who ask for the missing work (like this fool here who
wonders just what your correspondent offered to convince you).

>Is it 12.8 milliwatts, or is it 3.2 milliwatts?

EZNEC computes it at Eï¿½/R

Source record: 66832

The answer is 3 mW.

Any version of EZNEC can be used to do this calculation. The demo program will yield slightly less accurate results because of the limited number of segments(*).

I modeled two vertical wires, 1 meter high and 1 mm diameter, spaced 1 km apart, at 20 MHz, over perfect ground. The reported feedpoint impedance varies with segmentation, from 1.988 - j952.3 ohms at 10 segments/wire to 1.72 - j882 ohms at 100 segments/wire. Accuracy is likely to degrade with a larger number of segments, since even 100 results in segment length/diameter ratio less than NEC recommendations. I used 100 segments/wire for the test.

One of the choices in EZNEC of far field strength reporting is in V/m at 1 kW input and 1 km distance. For this antenna, EZNEC reports 300.8 V/m (RMS) at ground level.

EZNEC also permits setting a fixed power input, so this was set to 1 kW. The resulting source voltage and current are 21270 V. and 24.12 A. respectively.

A load of 1.72 + j882 ohms was placed at the base of the second vertical. EZNEC reports a power of 3.234 mW being dissipated in this load.

Care has to be used when analyzing the current induced in one antenna by another which is distant using numerical calculations. Errors can occur due to truncation and other causes when the ratio of distances between the two antennas is great relative to the segment lengths or to segment distances within one of the antennas. However, EZNEC gets virtually identical results when using mixed and double precision NEC-2 calculating engines, which indicates that the limit hasn't been reached and that numerical problems aren't occurring. (Another check which can be done is to reduce the distance between antennas by a factor of two. The power in the load resistance should increase by a factor of four.)

Another critical matter is the setting of the load reactance. The reactance is many times larger than the resistance, so a slight error in setting its value will result in a large difference in load current and therefore load dissipation. For example, if the segmentation is changed from 100 to 50 segments/wire and no other change is made to the model, the reported load power becomes 0.3917 watts. The reason is that the reported source impedance is now 1.756 - j891.4 ohms, while the load is still 1.72 + j882 ohms. Changing the load to the proper conjugately matched value of 1.756 + 891.4 ohms returns the load power to the correct value of 3.24 mW.

All given, I'd trust the reported load power to be easily within 10% of the theoretically correct value.

(*) Results for 10 segments/wire are 1.988 - j952.3 ohms for the source impedance, 300.71 V/m field strength at 1 km for 1 kW, and 3.24 mW in a conjugately matched load impedance in the distant vertical.

I actually found what I hope is a solution. The KANGA 33' Telescoping Fiberglass mast for $99 is guaranteed against breaking or shattering in winds such as I might encounter, free replacement of broken sections if this is so. Weighs only 4 lbs, base is 2 inches. K1CRA, the distributor, suggested that all I needed to do was mount this against my pipe mount with a 2X4 and U-bolts. He also distributes a sealing agent for permanent installations. With this, he said, all I needed to do was run wire up the mast and work against my pipe mount as connected to the overall ground systems.

Sometimes it is the obvious which is the hardest to conceive of. I always though high winds and high heights always needed big iron (or copper), but I never thought that something made of an aerospace material would be within my reach... let alone that of a ten foot Pole or a seven foot Texan...

I'll let you know how it goes...

Thanks,

The Eternal Squire

Correction: That should be 0.3917 mW. The error doesn't alter the
conclusion.

4342. The factor of 2

Newsgroup: rec.radio.amateur.antenna
Date: 2005-12-09 03:43:27 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <dnaugu$3l8$1@nwrdmz03.dmz.ncs.ea.ibs-infra.bt.com>
Source record: 66839

Roy,

My program requires antenna gains relative to isotropic to be entered.
To help discover where I was going wrong a numerical type program was
needed. Numerical programs do not need the intervention of fallible
human ideas about isotropes, mirror images and ground reflections.

I did not realise that EZNEC has the ability to calculate voltages and
currents induced in elements miles away from the radiating element.

But having the correct answer, I still have a problem. Praps you can
help me to solve it.

Staying with the same example of -

Frequency = 20 MHz.
Tx power = 1000 watts.
Distance = 1 kilometre.
Rx antenna height = 1 metre.
Rx antenna Rin = 1.944 ohms, including wire resistance.
Rx antenna -jXin is not needed.
Field strength = 300 millivolts per metre.

According to You, Terman and other Bibles, Volts induced in the 1
metre high antenna = 300 millivolts.

So we have a generator with open-circuit volts of 300 mV, with an
internal resistance of 1.944 ohms, with an Rx load resistance also of
1.944 ohms (which is in excellent agreement with EZNEC).

From which, power generated in the receiver = 11.6 milliwatts

BUT THIS IS SIX DB GREATER THAN THAT CALCULATED BY EZNEC.

From other considerations, and taking EZNEC's small errors into
account, it is EXACTLY 6.02 dB too large.

THE CALCULATION WOULD BE CORRECT IF THE VOLTAGE INDUCED IN THE
RECEIVING ANTENNA WAS EXACTLY HALF OF THE FIELD STRENGTH.

OR THE FIELD STRENGTH FROM THE 1KW TRANSMITTER WAS EXACTLY HALF OF THE
BIBLICAL VALUE OF 300 mV.

Where or how is the above calculation going wrong? A factor of 2 is
involved somewhere.

Thanks for your time and patience.

Reg, G4FGQ.

I agree with the E field computation at 1km. NEC2 calculates the normalized peak E field as 425.452 V/m, which gives 300 mV/m at 1 km. The input impedance, with 50 segments (#14 AWG, perfect conductor) is 1.747 - j823.798 ohms. The NEC output files shows the TRP at 1 kW.

For some reason I seem to get a different received power. If I model a 1 meter monopole, above a perfectly conducting ground, loaded at the base segment with the complex conjugate of 1.747 + j823.798, and an incident peak E field of of 1V/m. NEC computes the peak base current as 0.28636 A. Dividing by 3.3333, for the equivalent RMS current from 300 mV/m RMS gives: 0.08591 A RMS. power in the load then equals 12.9 mW, which seems to agree with Reg's figure.

Frank

PS -- NEC computes the gain of a 1 meter, ideal conductor, monopole above a perfectly conducting ground, as 4.8 dB (Ground wave). Also note the current in the base, from an incident peak E-field of 1V/m is 0.28636A, which through 1.747 ohms, is 0.5 V peak. This appears to agree exactly with Reg's rational.

Steve -and- For One and All,
.
The Quantum QX 8" and QX Pro 15" do show up on eBay :
But since they are still being made by that wonderful American
Craftsman and Electronic Artist "Gerry Thomas" under the
business name of "Radio Plus+" and still can be found at
the DX Tools .Com website => http://www.dxtools.com/
.
eBAY PRICES and AVAILABILITY - Kiwa -verses- Quantum :
The 'legendary' Kiwa Air Core MW Loop Antenna simply
gets part of its 'legendary' Aurora from the fact that it is no
longer being made; and therefore there is a limited number
of them and that number may be getting smaller with the
passing of each day, week, month and year. On eBay the
Kiwa Air Core MW Loop Antenna often sells 'used' without
any warranty for more then the original retail price of about
$400. This is in contrast to the Quantum QX 7.5" and
QX Pro 15" Ferrite Loop Antennas that still can be bought
"New" with a Limited Warranty for about $200 and $300
respectively. Question ? Why buy a used Quantum on
eBay without a warranty; when you can buy a New one
with a Warranty; unless you can get it at least 30%
cheaper on eBay. Maximum Price for the Quantum
QX 7.5" should be $140 +S&H and QX Pro 15" should
be $210 +S&H - IMHO otherwise Buy-It-New direct from
the Builder Himself - Again IMHO.
.
.
Now We Can Take The "Quantum" Leap To :
Gerry Thomas = Radio Plus+ = DX Tools .Com are all

Reg, G4FGQ wrote:
"According to textbooks, the field strength from 1 KW at 1 kilometre = 300 millivolts per metre."

Terman agrees with Reg`s signal strength produced by 1 KW radiated at a distance of 1 kilometer of: 300 millivolts per meter.

There are some conditions. The transmitting antenna is vertical and short compared with a 1/4-wavelength. It is nondirectional in a horizontal plane. The height of both antennas is low enough so that the space wave does not dominate propagation between them. Terman`s field strength derives from the equation first given by Sommerfeld and includes a factor aounting for ground losses.

==========
Folding is quite beneficial then at 1.9 MHz. How did you find what
the loss actually is? Did you model it? How far apart are the 3
wires?

Reg.

==========

Richard, thanks for the confirmation.

All you have to do now is calculate from the field strength the power available to a matched receiver at 20 MHz with a vertical receiving antenna 1 metre high.

If I tell you the antenna's radiation resistance is 1.758 ohms then you can forget about the frequency.

Reg.

I got to compare the Kiwa, the Quantum Qx and the 1 meter (diameter) Wellbrook 1530 loop on a Drake R8B. First of all, regarding the Kiwa, you don't need the regen if you have decent radio. Thus, screw the Kiwa since it only works on BCB. The Wellbrook beat the smaller Quantum Qx, but I don't know how it would compare to the larger Quantum pro. Then again, the ALA-100 and your own wire loop is less than the larger quantum.

Unless your radio sucks, I'd get the Wellbrook and go untuned. The advantage to the wellbrook is you get full HF coverage, while the Quantum only goes to 2MHz.

The ALA100 is billed as an outdoor very long wire version of the Wellbrook loops, but It works well with about a 10ft (length) wire, and exceptionally well with about 40ft of wire.
http://www.wellbrook.uk.com/ALA100b.html
The website doesn't explain the product very well. Here is one implementation:
http://www.lazygranch.com/images/radio/loop1.jpg
The amplifier is at the bottom of the loop.
http://www.lazygranch.com/images/radio/loop4.jpg
Not shown is the wallwart and the interface box you put near the radio.

I've hunted NDB's with the ALA100 using a loop no bigger than a pie plate. Of course, this is without 20 miles of the NDB.

For an isotropic radiator, is it correct to calculate the power flux density at 1Km at 1000/(4*pi*1000**2), and to find the field strength from FS in V.m = (power flux density * 120*pi)**0.5? That gives 173mV/m. It would be 245mV/m if the power were radiated uniformly in hemisphere.

300mV/m is conditional on the power radiated in a hemisphere and from an antenna with directivity (field proportion to the cosine of the angle of elevation).

Does that make sense?

There's a limit because of numerical precision, which I cautioned about in my last posting. But this problem is within its capabilities.

Yes, I'm very interested by the apparent contradiction. But I'm also seemingly getting some contradictory answers -- I'll have something to offer after I get it sorted out.

An alternative is to calculate the power collected by a lossless,
matched receiver as Pr=S*A.

In this case, S=0.3**2/(120*pi)

Kraus derives A (the effective apperture) for a short dipole to be
3/8/pi*wavelength**2.

This gives the power collected by the receiver as 6.4mW. If the
antenna and receiver were disected by the ground plane, wouldn't there
be 3.2mW developed in each half of the receiver load?

Here is a link to the DX Engineering page regarding this antenna:
http://www.dxengineering.com/Parts.asp?ID=880&PLID=161&SecID=78&DeptID=22&PartNo=DXE%2DSWA%2D070

There is a link on this page for the manual in PDF..You can clearly see
that they use a 3 conductor round cable for the antenna.
3 wire flat zip cord or twinlead with a third wire laced between the
two conductors is another approach, I think.
Jim

Source record: 66853

The reason for the contradiction is that I got the first result of 1 volt for the base of a 1 meter vertical wire above perfect ground in a 1 V/m field by using NEC with a plane wave excitation source which produced a 1 V/m plane wave field. The 3 mW value I got later for Reg's model was obtained by generating a 1 V/m field by putting a conventional source at the base of a second short vertical. And what I've now determined after a considerable amount of experimentation is:

The current reported by NEC-2 or NEC-4 to be induced in a wire (or the voltage in its center or between base and ground) by an impinging field created by another antenna is exactly half the value it is when the same field is created instead by an NEC plane wave excitation source, when a ground plane is present. This doesn't occur in free space models, which seem to produce correct results.

Unless there's some problem with interpreting the meaning of the plane wave source's field value, it looks like this is a bug in NEC-2 and NEC-4. I've posted a query on a mailing list frequented by the real experts at using these programs, and I'll report back what I find out from them.

We really need a sound theoretical basis for deciding what the value of induced current or voltage should be, for a final determination of which answer is right and which is wrong. I'll try to take a good look at that tomorrow.

But in the meantime, we do know that the field strength generated by a short vertical with a source at its base is being reported correctly by NEC. NEC programs have been used very widely for determining induced currents and field strengths, and my guess is that the plane wave excitation feature is relatively rarely used, and less so over ground. Consequently, I'll put my money on the result obtained by exciting a second antenna to generate the field rather than on the plane wave excitation source result.

If this conjecture is correct, then I was wrong when I said in an earlier posting that the voltage at the base of a one meter wire over ground was one volt when exposed to a one V/m field -- it should be 0.5 volt. I got the 1 volt result by using an NEC plane wave excitation source -- ironically, after first verifying that I got the known theoretical result in free space. And my more recent posting giving the power in Reg's example antenna load as 3 mW rather than 12 is correct.

I'll post more as I find out more.

I modeled it using #14 copper wire and EZNEC and comparing the
maximum gain to the maximum gain of a dipole.

> How far apart are the 3 wires?

EZNEC forced me to put them ~7 inches apart (minimum spacing on 160m).

Then S = 2.387*10**(-4) W/m**2;

and A = 0.119*(Lambda)**2, where Lambda = 20m. (p.44)

Therefore A = 47.6 m**2;

and Pr = 11.36 mW.

Since we have done this modeling of incident E-fields before, should there
not be some correlation with NEC2?

Frank

PS, your FORTRAN notation threw me for a second.

"A factor of 2 is involved somewhere?"

First place I would look is at the coltage actually applied to the receiver. If the antenna intercepts 1 volt per meter in a 1-meter antenna, only 0.5 volt is applied to the receiver. The other 0.5 volt is lost to reradiation in a matched antenna system.

Best regards, Richard Harrison, KB5WZI

Reg wrote:
"So we have a generator with open-circuit volts of 300 mV, with an internal resistance of 1.944 ohms, into an Rx load resistance of 1.944 ohms---."

You lose 1/2 the open-circuit voltage in a matched antenna`s radiation resistance. 1/2 the voltage in the receiver`s input resistance causes 1/2 the current. Received carrier power is only 1/4, or in other words, 6 db less than twice the voltage would produce were it available across the receiver`s input resistance.

0.15 volts squared over 1.944 ohms = 0.01157 watts on my Chinese calculator

==========

Yes Richard, I fully agree.

The trouble is that there are other ways of calculating receiver input power, seemingly equally valid. But they give an input power exactly 1/4 as big or 6 dB less.

Which way is correct? Terman, Kraus, Balani, their Bibles and numerous computer programs are all at loggerheads with each other. The very foundations of radio engineering are being undermined. ;o)

Reg.

Yes those black people are aren't they. Ooh you mean the white people?? yea. shocking they should complain about TNB. The thing is, acting as they do, these black "niggers" (as the statements go and also how other black people class their lower brothers) alienate themselves and its no wonder that most "racist claims" are dismissed as TNB so the real genuine cases of racism tend to make us just think "here we go again" rather than take the claims seriously. Remember the cry wolf story.
Some of the stories on that site put me off pick and mix or help yourself foods. Not simply because of the blacks behaving like animals but anyone with any disease could "play" with the food your about to pick up.... urgh..... mind you, seeing some of the staff in McDonalds and similar eateries puts me off their cuisine somewhat too. My god, if you knew some of the things that happens to your food before you get it you'd never eat again....

Regards,
Graham
(Ps. Apologies if you were eating then)

Several languages use ** as the exponentiation operator, FORTRAN was probably the first. C, the C-like languages and IIRC most of the Algol languages use **. The ^ operator used in VBA is a logical operator in most languages.

that web sight is hosted on a earthlink server and is in violation of
their hate speech TOS. I have writen to abuse@abuse.earthlink.net to
complain about it and get the sight pulled. good pple must be
vigilant against hate just like k1man always says.

I've received an authoritative answer about NEC plane wave excitation. When a 1 V/m incident plane wave is specified via a plane wave source and a ground plane is present, the field strength at all points is 2 V/m, not 1 V/m as I had assumed. The rationale is that the "incident wave" is reflected by the ground plane, doubling its strength.

The conclusions from this are that:

1. NEC reports that the voltage from the base of a 1 meter electrically short vertical wire to perfect ground in the presence of a 1 V/m field is 0.5 volt, not 1 volt as I said in my earlier posting in response to a question by Reg. I apologize for the error.

2. The power intercepted by the matched dipole in the problem recently posed by Reg is approximately 3 mW, not 12. The EZNEC calculation I described, which does not use a plane wave source, is correct. The same result can be obtained with NEC by using two antennas as in EZNEC, or with a 212 V/m (peak, equal to 150 V/m RMS) plane wave source which produces a 300 V/m RMS field at the loaded antenna.

This is a good place to give an additional caution to people using NEC for calculations. NEC uses peak, not RMS values for all voltages and currents. Power results will be off by a factor of two or four if a user mistakenly assumes RMS values. EZNEC uses RMS values throughout. When Reg posed the dilemma about the factor of four disparity in reported powers, my first thought was that this was the cause. As it turned out, it wasn't, but caution is needed. Results should always be given a reality check, as Reg has done. Any model -- and this doesn't exclude the mathematical models we often consider "theory" -- can be subject to many errors, including but not limited to misapplication, misinterpretation, and limitations of an approximation or numerical calculation.

To a certain extent, this comes back to a decision about whether
ground reflection contributes to the received power, and you are
saying that NEC assumes it does under plane wave excitation in
presence of a ground plane.

In "running the numbers", I note that the radiation resistance
indicated by NEC for a short dipole in free space is quite different
to that predicted by Kraus for a dipole with uniform current,
(Rr=80*pi()**2(L/Lambda)**2)!

Depends. What does "free" mean, in the real world?

It is not only freedom to, but also freedom from. Many countries have reasonable limits on things that are defined, in a strict legal way, as "hate speech" because their citizens demanded it. There are reasonable limitations on what you can say publicly as a citizen in front of other citizens just like there are reasonable limits on how you build buildings, drive cars and many other things that affect other citizens who have the same rights and privileges as you.

That is, there is a notion that I can invoke my rights as a citizen to *not* hear hate-filled diatribes that otherwise have no redeeming value. It is a balance between "freedom to" and "freedom from".

Citizens are all free to argue what these "reasonable limits" constitute, and whether a specific instance of disagreement on the matter falls under the law or not. You can have your day in court, if you like, but it is unreasonably to say that everyone has the "right" to say anything they want, anywhere they want. Doing so actually diminishes other people's rights.

In fact, the First Amendment is not an absolute. There is, and will continue to be, many specific instances where your First Amendment rights are suspended because the law of land demands it.

Anyway, if Earthlink is the hosting company, then it is their private space that they let their clients use. There is nothing in the First Amendment that guarantees any sort of free speech rights in this context.

Another context: if I invite someone into my house and they say or do something I disagree with violently such that I feel it doesn't deserve rebuttal or discussion, I am free to ask them to shut the hell up and leave. First Amendment rights do not automatically extend into private spaces in the US.

Similarly, if I have a web forum hosted in the US, and somebody posts things that I don't like, or do not wish other members of the forum to see, I am perfectly within my rights to erase the material and delete their account. They have no First Amendment rights on any such site, and bitching about free-speech is absolutely meaningless and without merit. There is *no* such guarantee of free-speech on such sites. Well, except possibly under very specific circumstances, such as if I was taking public money to run a public service.

A newspaper is under no obligation to print any letters to the editor, for example.

If the information we are discussing was hosted on a truly public forum, then First Amendment rights could be invoked. Countries where there are hate-speech laws usually side-step this issue by having the hosting companies act only as "carriers" with no editorial control over their subscribers. The onus for whether or not you are publishing hate-speech then falls to the government acting on behalf of "the people". The providers usually enforce only those terms and conditions that would impact other people sharing the service (i.e., technical issues like bandwidth use, hacking, and so forth).

Maybe we should be asking ourselves why we are in such a hurry to give up our private spaces, physical and virtual, to corporate interests.

It's been a while since you've done mathematical stuff in C, hasn't it?

C does _not_ use a '**' operator. If you want to raise y to the x power
you use "pow(y, x)".

this isnt a matter of crimenal law. it is a matter of the provider's
TOS which is a contract between the web sight and earthlink. I am
very surprised that you dont know about TOS and how a provider can
kick you off if you violate his TOS. sheeze.

The only way to achieve uniform current on a short dipole is with large capacity hats at the ends of the dipole. Otherwise, the current tapers nearly linearly from a maximum at the center to zero at the ends. If you'll look closely at Kraus' figure of the short dipole he analyzes, you'll see that it has capacity hats. Nearly all other authors analyze just a straight wire which doesn't have those hats, and consequently linear rather than uniform current distribution. And of course get quite a different result.

I'll bet you didn't include large capacity hats in your model. I haven't tried it, but you should get results much closer to Kraus' if you do. NEC analysis gives radiation resistance very close to theoretical when analyzing a plain straight wire dipole, but this isn't what Kraus does in his book. It is interesting, though, to see how much effect the wire diameter has on the impedance, and that the wire has to be very thin indeed to approach the theoretical impedance for an infinitesimally thin dipole.

I believe that's correct. Note that Kraus uses a plain wire dipole for his aperture correction, but a dipole with end hats (and therefore uniform current) for input impedance calculations. See my other recent posting for further comments.

It has, I tend to do most my ad-hoc stuff in Perl these days, and it
uses the ** operator. Perl is c-like, but as you say Tim, it did not
inherit the ** op from C.

Languages that lack an exponentiation operator are a right pain in the
butt, but there are lots of them.

An ISP is a private entity and does not have to allow it even if it is
legal. When you sign up with an ISP, you are entering into a contract and
agreeing to its terms and conditions. If the ISP says no hate speech, then
they can legally pull the page or sight and even cancel the user's service
due to violating the contract.

Hi, I plan to let everyone know. It has garnered a lot of interest.

The problem went away about 5 days or more ago. I reported on it. As several have predicted when I posted that, it's back!!! Interesting timing. I sent the C. Crane device back about the same time it returned.

I haven't been able to switch the old monitor back in, but in view of the return of the noise, I guess that's unnecessary. My shoulder is real cranky, so I haven't been able to make the swap.

Someone is sending me a corcom filter, but I haven't received it yet. I tried getting a tripplite outlet. I should have bought one while I was at HSC in Sacramento last week. They had several multi-outlet filters. Jameco and Digi-Key struck out. It's too far from here to jog down there.

The story continues. Stay tuned.

It's not illegal - no law has been broken. It is simply against
Earthlink's published guidelines. Mass market ISP's simply cannot
afford the free market fallout from such politically incorrect
hostings.

Hi Ross

300ft of RG213 maybe? Thats about 3.5dB loss at 30MHz assuming a 1.5:1
VSWR. At 14MHz its about 2.4dB loss.

LMR400 at about the same diameter as RG213 is just under half the loss.
Its also cheaper than RG213 but a bit harder to terminate into connectors.

RG6 may also be usable and much cheaper (being TV/CATV coax) as it has
only slightly more loss than RG213. Its 75 ohms though if thats an issue.

(http://www.ocarc.ca/coax.htm)

There will be a much lower loss if you use open wire feeder... You could
no doubt use broadband baluns at each end to change back to coax. You
could also make your own feeder probably much cheaper than using coax.

I seriously dont think the line loss figures in the coax mentioned above
are important for HF work. You are of course losing half your power at
higher freqs.

Cheers Bob W5/VK2YQA

I would recommend you take a look at Davis RF "BuryFlex" 9914. It is very nearly the exact same loss per 100ft (within a couple tenths of a db) as LMR400 and/or 9913. It can be directly buried in the soil with no other provisions needed. It has an abrasion resistant non-contaminating jacket that has a warranted 20 year service life. It is also quite affordable at about $.60/ft. It is very flexible and indeed is fine even as rotator loops. I use it on all bands I run from HF thru 6M and 2M. It uses standard UHF or N connectors as well. Loss per 100ft at 400MHZ is 2.9db

Check it out here....

1. http://www.davisrf.com/ham1/coax.htm#buryflex

At HF and with low SWR, anything of RG213 size or larger should be OK as regards cable heating... but in reality you are not aiming to reduce the losses "to a minimum". You're actually making a three-way balance between losses, availability and cost.

(Re availability and cost: people in the USA should note that Ross is in New Zealand. Coax is heavy, and international shipping costs are horrendous, so Ross has a much narrower range of options than you do.)

"Cost" will also include the cost of repairs and replacement - and this can be a big consideration with a long run of cable because it's extremely important to keep the jacket free from any damage where water can get in. Capillary action can suck water into the braid over very long distances from the initial location of the damage, and corrosion of the braid can drastically increase the losses. So even minor physical damage can have big electrical consequences, and can effectively destroy a long section of line.

I'm in a similar situation here, with a new tower and LF verticals. The cables will have to run a long distance over rough land covered with thorns and sharp stones... and it's usually wet too. For all those reasons, I am not going to use braided coax, but will try *very very* hard to locate some surplus hardline.

The advantage of foam-filled hardline is that it's largely immune to minor damage from the outside. If the plastic jacket is cut or even removed completely, it doesn't matter at all because you still have solid copper to keep the water out. And even if you take a slice off the copper sheath with the mower (BTDT), water will not migrate along the inside because the closed-cell foam is firmly bonded to the inside surface of the sheath.

You certainly don't have to buy hardline at new prices - though even there you might be pleasantly surprised (for example there's an outlet in VK-land whose prices are very reasonable). Your options will depend on what's available in ZL, and to find out you may have to tap a few contacts.

For example, in the UK there's a lot of surplus hardline is coming out of cellular, broadcast and other VHF/UHF/microwave sites as they are being upgraded to the next generation. A lot fo this goes straight to scrap copper, but some gets diverted into the surplus market. Short lengths appear quite often at radio flea markets ("rallies"), and if you ask, the guys generally have much longer lengths back home at much lower prices.

(In the USA they also have aluminium-jacketed cable TV hardline. It doesn't exist in the UK, but if it's relevant in ZL there are people in this newsgroup who know about it.)

Crazy as it may sound, the larger sizes of hardline can be cheaper on the surplus market than the more popular "half-inch" size. The larger cables are more difficult to transport and less convenient to handle, so there are fewer buyers and that drives the price down. Even so, 2-3 people can handle the lengths you are considering, and in a fixed installation you only have to lay it once... and then you really could say you've reduced the losses "to a minimum".

I found another source (Ramo et al) which directly gives the ratio of power in the load of a matched receiving antenna to the power applied to a transmitting antenna, in terms of the effective apertures of the antennas. This doesn't require the intermediate step of calculating field strength. The equation is:

Wr/Wt = (Aer * Aet) / (lambda^2 * r^2)

where:
Wr, Wt are received and transmitted power respectively
Aer, Aet are the receiving and transmitting antenna effective apertures
lambda = wavelength
r = distance between the antennas

Note that effective aperture, like other measures of an antenna pattern, is a function of the direction from the antenna. So this equation is correct regardless of antenna orientation as long as Aer and Aet are correctly calculated.

Letting

K = 3/(8 * pi) ~ 0.1194

we can write the equation cited by Owen for effective aperture of a short dipole in its most favored direction (broadside) in free space as

Ae = K * lambda^2

(This is the effective aperture of an infinitesimally short dipole. However, it changes very little with length when the dipole is electrically short. The effective aperture broadside to a half wave dipole is only 10% greater.)

Then we get that

Wr = Wt * (K^2 * lambda^4) / (lambda^2 * r^2)
= Wt * K^2 * lambda^2 / r^2

For Reg's example, lambda = 15 meters and r = 1 km. Since this is a free space analysis involving dipoles so far, I'll apply 2 kW (Wt) to the transmitting dipole, resulting in Wr = 6.412 mW.

Now we can split the model exactly in half with a ground plane. On the top of the ground plane, the transmitting antenna has exactly half the applied power, or 1 kW, which is what we had in Reg's example. Half the load power is in the upper plane also, so we have 3.206 mW for the load power in Reg's example setup. This is very close to the 3.234 mW result from the EZNEC model.

The antenna's effective height (that is, the ratio of induced voltage to field strength) has been at issue. As Reg pointed out, ~ 3 mW at the load requires an effective height of 0.5 meter for the 1 meter high antenna. (I incorrectly gave it as 1 m in an earlier posting.) I did find an explicit equation for effective height for a vertical over perfect ground, in King, Mimno, and Wing (Dover edition, p. 165). This also confirms that the correct effective height is 0.5 m for the 1 m electrically short vertical antenna over ground.

I'm satisfied that we have the answer to Reg's question. It's been an educational process for me -- thanks for posing it.

One final note, regarding the NEC applied plane wave. My earlier statement that the resulting field is twice the plane wave source magnitude when a ground plane is present is true only when the plane wave is applied over perfect ground at exactly grazing incidence (zenith angle = 90 deg.). If applied from other angles the resulting field strength will be different. If you apply a vertically polarized wave over a ground plane, I believe the resulting field strength will look like the pattern from a vertical radiator over a perfect ground plane -- strongest when applied at the horizon, decreasing when applied at higher angles, and dropping to zero if applied from directly overhead. I haven't confirmed this, but believe it's necessary in order to get a receiving pattern that's the same as the transmitting pattern. So use it with caution when a ground plane is present, and don't casually make assumptions about the resulting field.

I've got some of that which I purchased new, and did some extensive tests on it with a network analyzer. The loss varies all over the map depending on how you coil, bend, or flex the cable, and I never saw loss anywhere near as low as the spec says. A typical value at 400 MHz was more like 5 - 5.5 dB/100 ft. Glad you're happy with it.

Hi Bob,

I can ge tubing in the size made of PUL500 which is an industrial grade of
Fiberglass, but 20ft must be purchased.

It is expensive. However if you are looking for 1" dia solid that could
arranged as I ourchase it on a regular basis.

Well, thank you Mary Whitehouse.
Lets hope you also complain about the ethnic sites disrespecting white people. The thing is with niggermania.com although some of the language used is of a racist nature, most of the stories ring true to many of us who have lived in black areas which always seem to turn into ghetto's wherever they are. Racist view or general observation? Ill let the readers decide.

Regards,
Graham

Ps. The site has nothing to do with me nor do I endorse it in any way.

I knew of a spoof site that a girlfriend I once had made and the only
defamatory thing on it was a single link to the BNP party which is a
legitimate and legal party in the UK and the host deleted her website
immediately for this. No warning or anything it was simply removed. That was
a Yahoo Geocities site. I personally find that a disgusting attitude for
them to take as it took her many weeks of hard work to make her site and
they never even warned her first.
Free speech seems to only apply for the ethnic minorities.

Don't get caught up in the "spelling" wars. I noticed that my fingers had typed the wrong one just after I hit the send button.

Free speech has never meant that a person can say whatever they want, wherever they want, whenever they want. There are many laws defining what you can and cannot do. For example, I can stand on a public sidewalk (i.e. publicly owned properties) handing out flyers all I want to so long as I am not doing anything illegal. On the other hand, if I want to hand them out in the shopping center (i.e. privately owned, not paid for by tax dollars), I must have the permission of the shopping center owner/management. The subject of the flyers is irrelevant. Our tax dollars do not pay for the ISP and so as a private entity they can limit usage of their service.

A business can legally prevent its employees from handing out political material (campaign buttons, flyers, etc) on its premises. If they have such a policy (and this has been clearly published to its employees), they can fire an employee for doing so and it does not violate the employee's right to freedom of speech.

To really understand the First Amendment and what freedom of speech really means, one needs to study it in the context of history. It had been a common practice for governments and rulers to throw people in jail simply for criticizing the government or even simply disagreeing with its policies. The First Amendment was crafted to protect people from being jailed for such and to enable and even encourage open discussion and debate on issues. It was not intended to protect libel, slander, fraud, speech encouraging violence, etc. Nor was it intended to force people to listen to someone else's free speech. If someone comes on my lawn and starts making a speech, I can call the police and have him escorted off. Freedom of speech does not allow him to force me to listen or to use my property.

The extent to which freedom of speech applies is endlessly debated and the amendment endlessly interpreted. All that people can really agree on is that it was not intended to allow an "anything goes" type of approach. They cannot agree on what it does cover however.

Correct! The First Amendment does not cover *anything* a private
person or a private company does. It applies *only* to actions by the
government.

That obviously eliminates any restrictions an ISP might put into their
usage agreements from "breaching the First Amendment. I'm always
amazed at the number of people who don't understand the Bill of
Rights. Walt must have been asleep in the back of the room when his
teacher talked about the Constitution.

>etc).

I suppose you have the Coded Orthogonal Frequency Division
Multiplexing (COFDM) standard there.

(Editorial mode on)

Our idiot government is forcing 8-VSB (8-level vestigial sideband) on
us and multipath will be the death of my off-the-air TV watching.

Furthermore, my wife and rarely watch anything live (except for local
news), but use two DVRs for time shifting and commercial elimination.
So with my system, if I can get a picture at all, I would need three
STBs (set top boxes) that are programmable or a couple of new digital
recorders and a new TV set. (If I was poor enough, my idiot
government would buy this stuff for me, but instead, I believe I will
be taxed to buy it for someone else.)

And then they are changing the aspect ratio so my 35" screen is
obsolete and any replacement would have a smaller screen if I want to

keep it in my $7,000 piece of furniture.

One of my U.S. Senators (McCain) is actually leading this effort, "In the interest of public safety" because he says the analog TV frequency spectrum will be used for emergency communications. Ha ha. The government wants to auction this spectrum off to the highest bidder(s) and it won't be the local police department.

Another example of what you get when you have politicans making technical decisions.

(Editorial mode off)

Walt's in the UK. I seriously doubt if they teach the US Constitution
there. They may do a brief outline just as we get a brief summary of
Britain's form of government but it's unlikely they would go into any depth
on it.

Anyone talks about US Constitutional free speech without knowing
that the First Amendment is *only* a guarantee against abridgement by
the government itself, is a moron.

>
> where:
> Wr, Wt are received and transmitted power respectively
> Aer, Aet are the receiving and transmitting antenna effective apertures
> lambda = wavelength
> r = distance between the antennas

Kraus "Antennas" also describes this equation. He refers to it as the
"Friis transmission formula" on pages 48 and 49 of the second edition.

I believe a better way to describe this situation is that the plane wave
field strength does not go to zero, but rather the effective aperture of
the antenna goes to zero as the plane wave is applied from overhead.
This does not change your conclusion with respect to antenna patterns.

The oblique-incidence plane wave equations are slightly messy, but they
are well described in treatments of waveguides.

Horizontal effect of constitutionally guaranteed rights is an element of many countries' legal systems. When I studied a bit of law in Ireland, I learned about constitutional torts. The idea is that, take free speach, if torts law does not protect my right to free speach when it should, than this is a shortcoming on the part of the state, i.e. the court and the legislature. To rectify this, the plaintiff, when suing another private person in tort, can base his case on his constitutional right. In tort, there are about a dozen or so precedents where this reasoning was upheld.
In my own country, the Netherlands, the constitutionally protected rights do not have horizontal effect directly, but they are used for the interpretation of open norms in civil law, such as the public order exception to free contracting and the due care requirement in tort law.

I hope you learned something,

Martin Holterman

I don't know what you two have going but his "analysis" flies in the face of every other review and/or comment I have ever read about Davis 9914. As well as my own experience of low loss and great performance. I have several bends in my runs of 9914 and no adverse swr.

Have you looked at all the positive user's reviews at eHam about it? Not a single negative remark..
1. http://www.eham.net/reviews/detail/4515

One might also want to check this link for another endorsement of Davis BuryFlex 9914
2.
http://lists.contesting.com/archives//html/Towertalk/1999-08/msg00010.html

The again one could just read what is posted at this link at the eHam Elmer's Forum - all very positive
3. http://www.eham.net/forums/Elmers/38717

I'm not saying Roy is misstating what he saw. I'm saying what he saw misstates the real quality of this coax.
1. Maybe he got a bad piece
2. Maybe he had a loose connector
3. Maybe he didn't calibrate the network analyzer
4. etc etc etc....NO ONE else I can find dislikes this 9914!!!

Except that I'm in the USA so I have nothing to worry about.

The UK is pathetic. Though I'm descended from Brits, I realize why my
country declared independence. America may have its problems, but I
expect that British culture will be extinct within a century, having
first been turned into an joyless Orwellian police state before finally
collapsing into anarchy.

"He did not know how long she had been looking at him, but perhaps for
as much as five minutes, and it was possible that his features had not
been perfectly under control. It was terribly dangerous to let your
thoughts wander when you were in any public place or within range of a
telescreen. The smallest thing could give you away. A nervous tic, an
unconscious look of anxiety, a habit of muttering to yourself - anything
that carried with it the suggestion of abnormality, of having something
to hide. In any case, to wear an improper expression on your face (to
look incredulous when a victory was announced, for example) was itself a
punishable offense. There was even a word for it in Newspeak:
'facecrime,' it was called."

>Elmer's Forum - all very positive

Being positive and being correct are not the same thing.

>I'm saying what he saw

Roy and anyone else is perfectly capable of speaking for him(them)self
and telling us what he (they) saw. Interpretation is prone to
transcription error, a frequent element of testimonial and
endorsement.

>1. Maybe he
>2. Maybe he
>3. Maybe he

There are no maybes. Within this group there are experts in every
sense of the word that are credentialed and experienced. Among this
group are several Metrologists who do or have done these kind of
things (determine loss) for a living.

>4. etc etc etc....NO ONE else I can find dislikes this 9914!!!

Roy is not offering an expression of personal taste, he is merely
stating that products often suffer claim inflation, which we can
observe to be inflated further by uninformed testimony. He offered
one very specific counter-claim in a region of RF that is especially
prone to error from the horde of eham testifiers. Their possession of
exotic tools does not confer upon them the ability to correctly
determine power (and by that extension loss).

If you want to challenge a technical statement, you have to go to the
statement and examine it by parts. Ask for data. Ask for the
references (and I don't mean chapter citations). Look at the
computations. Rebutting with testimonials is useless as they only
serve vanity.

> Except that I'm in the USA so I have nothing to worry about.

Id say you had quite a lot to worry about. Maybe not in respect of the content of your website (if it is yours of course) unless some of these black people get ahold of you of course, but everything else, gun crime, immigration, corruption... its all there in much larger amounts than in the UK.

> The UK is pathetic. Though I'm descended from Brits, I realize why my
> country declared independence.

Your Country is becoming a cess-pit of multi culteral misfit lowlifes. Declairing independance from the UK can only benefit the UK so I wouldnt get too excited about that. The website shows that only too well.

America may have its problems, but I
> expect that British culture will be extinct within a century, having
> first been turned into an joyless Orwellian police state before finally
> collapsing into anarchy.

Anarchy you say? Like the NO saga and the ghettos in nearly every City in your Country you seem to forget about. The UK is a reasonably tolerant Country as far as Immigration and integration goes but the USA.... I honestly believe the UK is in a much stronger position in holding onto its identity than the US.
That said my sympaties go out to the genuine American people having to put up with this.

A George Orwell fan.... that explains the previous barmy statement. So many people seem to be convinced they are being filmed and watched by some

organisation to bring them down or fit them up with some crime. As if anyone in reality gives two hoots about them or anything they do.... too full of their own importance which is realistically rated at 0 to such organisations if, infact, they actually exist. George Orwell.. hah...

Regards,
Graham

It depends whether you are attempting to gain by deception I would say on
that account. Pop stars always use alias's, like Harry Webb. Come to think
of it, Shirley Crabtree too as his known name was Big Daddy. So many people
in different walks of life go by different names these days.

Its definitely a crime to spell Walt as Wlat though ;o)

>Hard line excepted due to cost.

Ross,

Interesting to see use of such a long line. We have been reliably
informed that nobody uses more than 75' or so!

Starting with the question "what is wrong with commonly available
RG213", you would expect a loss around 2.4dB in a 100m run (200' + 70'
+ 30' tails) with an average VSWR of 1.5.

Given that the lowest ambient noise level on 20m is around 20dB above
typical receiver noise floor, the impact of 2.4dB of loss on receive
is insignificant.

On transmit, you will lose about 45% of your power in the line, so
with your 2KW (output?) amplifier, you will still have 1100W arriving
at the antenna. Will that do the job OK?

Is ladder line the panacea? Wireman 554 directly connected to a 50 ohm
load would have a loss of ~1.7dB and a little extra for baluns brings
you close to 2dB, so it is not a whole lot better than RG213. However,
if you used a 9:1 balun at each end, you would expect line loss of
~0.6dB and a little extra for baluns brings you close to 0.8dB. Now
that seems respectable. Problem is that you live in the land of the
long white cloud, and ladder line performance is degraded
significantly when wet, so it might not be acceptable in your
situation when wet.

Lets look at home made open wire line using 2mm copper spaced 150mm
for a 600 ohms line. If you used the same 9:1 balun at each end, you
would expect line loss of ~0.2dB and a little extra for baluns brings
you close to 0.4dB. Now that seems quite good. Anecdotally, such an
air spaced line is not affected significantly by weather / water, but
that will depend on the quality of the insulators and your rigging
methods.

Remember that the open wire solutions above need to be tuned feeders
or you will need an ATU. I suggest that you will need the ATU for
multi band operation, so you should allow another tenth of a dB or so

for ATU loss.

Someone will probably suggest that LDF6-50 (32mm (1.25") hardline) could achieve 0.3dB loss, but could you afford it, would it be good value?

Owen

I had a bad experience with Belden 9913 and if Davis 9914 has the same mechanical properties, be careful. I taped some 9913 to a mast and sometime later discovered it had been squished flat from the tight wrap of electrical tape. I have also seen people ty-rap 9913 and destroy its shape. If Davis 9914 has the center conductor suspended by a thin spiral thing like 9913, I would not be surprised with varying performance when bending it. Here is some coax that looks like better performance than 9913 or Davis 9914 (2.7dB/450MHz/100ft) has the same Polyethylene outer jacket as Davis and is cheaper. Check

>If Davis 9914 has the center conductor suspended by a thin spiral
thing like 9913,

Davis BuryFlex 9914 does not have the center conductor suspended by a thin
spiral.
1. http://www.davisrf.com/ham1/coax.htm#buryflex

It amazes me that no one else (that I can find) has found Davis BuryFlex to
be "bad coax". It has been in production well over 10 years.
Moreover I am amazed how many of you are non-thinking lambs following along
head-to-tail after your shepherd.
And also Davis emphasizes in it's data that this coax is flexible enough for
rotator loops and yet one guy says it is "bad coax" and so everyone falls to
their knees and worships accordingly?

And as far as data goes...is this guys data more accurate then the Davis RF
company that has been in the wire and cable business
with engineering professionals on the payroll since 1980? Sheesh......take
off the blinders people.....thousands of miles of Davis 9914 have been
installed by government,commercial and amateur stations and just now we find
out it's "bad coax" after more than 10 years?

Somebody is asleep at the switch.......

I'd be glad to compare results and methodologies with anyone else who
has measured this coax. It would be particularly interesting and
educational if someone else's results are significantly different from mine.

Please, folks, I didn't say that Davis BuryFlex is bad. I said that careful measurements of the one 100 foot piece I have show it to have much more loss than the specification indicates, and that the loss is variable with flexing and bending. It's possible that the piece I have is somehow defective. Everyone can interpret and act on this or not as they choose. But I certainly won't be installing this brand and type of cable in a critical application without carefully testing it first.

Huge numbers of ravingly positive testimonials can be found for CFA antennas, cryogenically treated oxygen-free speaker cable, astrological forcasts, and homeopathic remedies. I'm not interested in testimonials for those or for coax cable either, all for the same reason. But I'd love to see the results of anyone else's measurements.

The 100 foot piece I have was purchased several years ago from The Wireman, so I know it's the genuine article. (It's also marked as Davis BuryFlex.) It's been inside and unused since.

No. My experience is that the vast majority of amateurs don't have the ability and/or confidence and/or interest and/or equipment to make good measurements. And lacking the ability to measure it, very few would be able to discern the difference in loss. If my measurements are typical, commercial and government users (if there indeed are any for this particular cable type) would quietly reject the stuff on incoming inspection and order something else.

I do have a high degree of confidence that my measurements are accurate. I took a lot of care in characterizing the cable before using it for making remote antenna impedance measurements in the course of a consulting job. But it's entirely possible that the particular piece of cable I have is defective. That would just point to a quality control problem rather than overzealous specsmanship.

In your query of Davis, I hope you asked them if they routinely test production batches for loss, and if so how often and when the last test was run. It's possible that something in their process changed relatively recently.

If no other reader of this newsgroup has some of this cable and the ability to test it, I'll see if I can arrange for someone else to make measurements and post results.

Roy the kind of test results you cited would be extremely evident whether someone has a network analyzer or just an swr meter.
That defense is sorely transparent in my opinion. To suggest that most amateurs would not even have any interest if their bent or coiled 9914 suddenly jumped off the scale for loss and mismatch is ludicrous to say the least.

Let me be clear ...I am not disputing what you claim you got as test results. My conclusion is either the 100ft length you had was bad or something skewed your calibrated setup. My career was in microwave r&d and I know that it takes repeatable test results to form a valid, verifiable and publishable data.
This is not personal Roy....but it is somewhat stimulating.

Roy, this seems a case of brand loyalty vs objective measurement and
evaluation (albeit on a single sample).

You will change your mind based on more measurement data, either
strengthening your existing opionion or changing it.

Those with brand loyalty already know all they need to know, life is
comfortable.

You are talking different languages, and the only way there will be
agreement is if you capitulate (which would be unprincipled in the
absence of evidence).

Owen

I remember the fierce debates over 9913, there were nearly as many
words written about how fabulous it was, as there were words written
on how to keep water out of it.

I needed conventional low loss coax on the job a few years ago. Boss was paying for it, so I was not pinching pennies. Best I could find was the Times LMR400. As I recall, the center conductor is #9; so, it may not fit some brands of N connectors. Unlike the 9913, this will not soak up water. The loss at 50 MHz is 0.9 db, vs 1.6 db for 213 (100 feet). I know you want 20 meters, but 50 MHz is the lowest frequency I have any numbers for.

Owen it is NOT brand loyalty. It is the publicly published data by RF Davis (for the past 10+ years) vs. Roy's one-shot test setup some years ago. I'm not out to discredit Roy...I even shook his hand once at a Hamfest.

We should be a little suspicious of manufacturers claims. Davis' can
be expected to support their product.

Roy's single poor experience is concerning, indicating either a
quality control issue, or more general non-compliance with spec (both
are issues for Davis). An independent test of stock cable and possibly
Roy's sample would be most interesting.

I know I have made measurements and adjustments at times and in
searching for possible explanations, the cable quality is on the
radar. In one of those cases, a mobile installation could not be
trimmed properly, and the Taiwanese RG58 centre conductor was so far
off centre, it was nearly touching the braid.

We have all cut cables up and found inconsistent braid weave, open
braid weave, voids in the dielectric, faulty stranding of inner
conductor, off centre centre conductors. It is those kind of issues
that downgrade a suppliers reputation, not their ability to select a
good cable sample for laboratory measurement.

Perhaps if you're a whiz, you should perform some measurements so you
can report first hand your experience.

We don't see the Davis stuff on this side of the world. The concept
seems a good one, PE sheath, braid+foil outer, foam dielectric,
stranded inner, but you have to ask yourself why they haven't
displaced Heliax and its copies. I suspect the reasons include IM and
noise issues associated with the braid+foil, mechanical issues with
the foam, and resistance to water. Experience with noise and IM
problems with braid+foil coax in fixed installations makes me wonder
how it stands up in a rigorous test of flexing for a rotator loop, not
anecdotal evidence, but a structured test.

Owen

Would you really notice if your cable loss was about 3 dB higher than specified at 400 MHz and if it varied by a dB or two when the cable is flexed and bent? What measurement equipment do you use which would cause this amount of extra loss to "jump off the scale"? And what causes you to think that increased loss would cause mismatch to "jump off the scale"? Increased loss will improve, not degrade, the impedance match.

> Let me be clear ...I am not disputing what you claim you got as test
> results. My conclusion is either the 100ft length you had was bad or
> something skewed your calibrated setup.

What you have as evidence is Davis' spec on the one hand, and my measurement report on the other. You've chosen to believe that Davis' cable all meets its published specifications. I have exactly the same evidence, but know my capabilities and that of my equipment, so I believe my measurements -- but always keeping in mind that it's a single sample. Additional measurements made by someone else on another piece of the cable would increase the knowledge base, although I'm sure there are people who would choose to ignore the evidence no matter how much is presented.

> My career was in microwave r&d and
> I know that it takes repeatable test results to form a valid, verifiable and
> publishable data.

That's great! Then you have the background to be able to make decent measurements, and you said you're using some of the cable. Why not just measure the loss in a length of it and report your results?

> This is not personal Roy....but it is somewhat stimulating.

I hope it's caused a few people to think a bit about how they evaluate evidence to determine the truth of a matter. It's something which too many people are woefully unable or unwilling to do.

Roy what kind of coax do you recommend along the same type ? I soon plan on putting up several beams, tribander for the low bands, 6 meter, 2 meter and a 432 antenna. Should be running about 125 feet or so. While I know hardline would be best for the VHF , I don't want to (can't spend the money, easy to install for the rotator) so I want to stay with one of the 9913/lmr400 types. I have had a piece of 9913 up for about 10 years and it seems to be ok, no water I can tell, I still would like to go with a solid foam type instead of the hollow core .

Just looking at the specks and advertising can sometimes be deceiving.

But I don't care what they don't like, ISPs are a dime a dozen and I can
easily find another one. Actually, I'm inclined to subscribe to Altopia,
they fiercely protect their customer's identities and really have no TOS
other than turning over customer records if subpoenaed by an American
court. Threatening to kill people is a crime and would qualify, but
offending people is perfectly legal under U.S. law.

Owen with all due respect there is no "question" why 9914 has not replaced Heliax and that is due to loss factors. BTW 9914 is impervious to water in and of itself..so evidently you have not done much homework on this particular coaxial cable. Davis 9914 is recommended for rotator loops. Your supposed quandary about "9914 replacing Heliax" is contrived in my opinion to murk up the waters of this issue and maybe steer focus away from what obviously, at least to me, is an unfortunate one-time testing experience by Roy.

Yes I suppose we should always be "suspicious" of manufacturer's claims but do you exercise that philosophy across the board? How about the tires on your car? How about the prescription medicines you may take and also over the counter meds? How about those fast food burgers? How about your drinking water? Are you as equally "suspicious" of these products or is this philosophy of yours only revealed to others when you want to discredit someone else's data. I think the later and not the former sir.

Owen....I give you a salute for being an obvious "spin doctor" for Roy's one time, one sample, one conclusion, years ago test cycle.
A job well done on the surface..however the underlying facts remain. Davis BuryFlex has been sold for well over 10 years in the "real world" and these same real people, government agencies, municipalities, and service agencies have used thousands of miles of it with no apparent issues. Cite similar tests to Roy's and I'll reconsider.

As for me I'll go with the Davis data, once it arrives, and do a calibration standards trace on their test station. Was Roy's test bench's calibration traceable? It is preposterous you would continually cast aspersions towards a company that has been in the wire and cable business for over 25 years and promote and crusade for a one time shot-in-the-dark independent so-called "test".

You do not fool me sir....best regards.....

-ps How many times do you think Davis has tested their 9914 in the past 10+ years?
More than the one single time Roy has perhaps?

To find ALL electrical characteristics and performance of
solid-polyethylene transmission line, use program COAXPAIR, from audio
frequencies to UHF.

Accuracy is of the same order as physical dimensions can be measured.
Use a micrometer to measure inner conductor diameter and diameter over
insulant. Or just guess at it. No need to unwind the cable off the
drum!

In a few seconds, download COAXPAIR from website below and run
immediately.

I wasn't going to go that far, and I realize it's probably not common in ZL but I've bought lengths of LDF5-50 at ham flea markets. The last purchase, claimed to be about 10 meters worth, but by my estimation at least twice that long, and new and unused, cost me $10 U.S.

Most of this stuff is leftover or removed from commercial two-way or cell phone use and shows up all of the time. LDF4-50 is even more common. I often buy short pieces that have been cut down, just for the connectors that are still on one end.

I find it curious that Andrew cable is seen so often at these events and yet I've -never- even seen a piece of Davis cable, dispite the claims that miles of it are in commercial use.

I agree with Ian's comments, the larger sizes are often available here
as they are less attractive to hams. But if you buy 3 or 4 lengths of
LDF5 or LDF6 and use connectors to join them, you will run into big $
unless the connectors come very cheap.

Andrews has some braid+foil / foam coax, and they perform roughly
similarly to LMR400, BuryFlex and 9913.

To my mind LDF4-50 would be acceptable in this configuration, and the
great advantage is that if water gets in somewhere, it doesn't wick
right down the cable. I haven't handled BuryFlex, and I saw the claim
it is waterproof, but I suspect it is not as waterproof as Heliax type
cable where the closed cell foam dielectric is bonded to the inner and
outer conductor with an adhesive, and there is no braid to form a
natural wick.

I am in the throes of replacing feedline on a HF dipole to repair
damage by birds. The birds don't seem to eat PE irrigation tube, so I
have fitted RG6 with a W2DU style balun inside 13mm PE tube to defeat
the birds. The birds have attacked the LDF4-50 on the VHF/UHF
antennas, but even if they make a hole in the copper, it doesn't seem
to affect cable performance measurably, probably because the water
can't travel up and down the cable from the hole.

Still, parts of ZL have Keas, and they will eat anything, especially
rubber or plastic! So I feel for our ZL friends running coax over 60m
of ground.

BTW, I added BuryFlex to my online line loss calculator, 9913 and C2FP were already there.

I still like the open line option, but it will be real important to use effective baluns to adequately ensure balance. It used to be common commercial practice when HF Radio was used more widely for international telephony / telegraphy.

I don't care about free speech as much as about freedom of assembly
and freedom to circulate. For instance in China another big bunch of
folk have recently been killed by the army in a public gathering. This
is doubly worrisome when Air Marshals here start to get trigger happy
and kill innocent people for no apparent *good* reason other then some
perceived abnormal behaviour. Many people tend to behave *abnormally*
in my opinion. This is a recipe for disaster and people should start
reconsidering the marshals' abnormal behaviour real soon!

As expected, the discussion appears to have fizzled out.

Having for the first time allowed myself to be led astray by the
academic professors and authors and their Bibles on the subject, I
still have the problem of correcting a bug in my computer program. The
program itself, GRNDWAV3, is too interesting, useful and educational
to simply withdraw it.

Lets not be confused by fallible human ideas and notions on -

Reflections from the ground.
Mirror images in the ground.
Antenna gains relative to isotropic.
Antenna gains relative to isotropic with a ground plane.
Antenna gains relative to isotropic of dipoles.
Half hemispheres.
What on Earth is an isotropic antenna anyway?
And now we are being introduced to waveguides.

Thanks to Roy's investigations and clarification, the solution to my
problem is perfectly simple -

"The effective height of a short vertical antenna is half of its
actual height and the voltage induced in it is half of the field
strength in volts per metre."

Which gives the correct answers from my program.

And which was proven and well known 100 years ago by the early radio
engineers who were really the first amateurs in the game.

Having got that off my chest, I can now finish the second half of a
bottle of Australian, Bantock Station, Special Reserve, Cabernet
Sauvignon Shiraz which I can thoroughly recommend.

What I wonder is the legality of that 1894 book "Ten Little Niggers"
on the site. If "hate speech" is ever criminalized in the USA, does
that mean all historical literature must be destroyed to comply with
the law? Keep in mind that schools have banned books by Mark Twain
because he uses the word nigger, but in a historical perspective his
use is not racist because that simply was the word used at the time.

Take "negro," for instance. We still have "United Negro College Fund"
and I think they recently opened a hall of fame for the "Negro League"
of baseball that operated in the first half of the 20th century before
sports were integrated. The word had no derogatory connotation then,
but today it is considered a racial slur as vile as "nigger." Even
the "Afro-American" they insisted replace negro is now taboo and we
are told we must call them "African-Americans." In a few years that
term will be forbidden, it will be considered racist to even mention
their race and that they are simply "Americans."

So when hate speech is outlawed, will all books written prior to the new era of enlightenment be burned? You mention Orwell, so I imagine history will be "rectified" to purge it of all things unorthodox.

Here's a relevant quote. The working title for the movie "Brazil" was "1984 1/2" so I suppose the Manifesto could be "1984 3/4":

"When someone interprets as derogatory almost anything that is said about him (or about groups with whom he identifies) we conclude that he has inferiority feelings or low self-esteem. This tendency is pronounced among minority rights advocates, whether or not they belong to the minority groups whose rights they defend. They are hypersensitive about the words used to designate minorities. The terms 'negro,' 'oriental,' 'handicapped' or 'chick' for an African, an Asian, a disabled person or a woman originally had no derogatory connotation. 'Broad' and 'chick' were merely the feminine equivalents of 'guy,' 'dude' or 'fellow.' The negative connotations have been attached to these terms by the activists themselves."

....

What is "offensive"? Describe it. According to the hand-wringing Liberals,
"offensive" is anything that they, in their elitist mindset, disagree with
and deem to be politically incorrect. Enter the Thought Police.
And, for instance, when one or more of us stands up to the PC crowd we are
labeled as Right Wingers or, in their weak PC minds, as RightWing Religious
Nuts.
Oddly enough these Liberals are all about censorship.
I love it when some limp-wristed whiner comes along and mewls, "I find that
offensive." So what? Big fuc*ing deal! Who is he/she to determine what the
rest of us can or cannot say or even feel?
To date I have found nary a word in our Constitution that has anything to do
with protecting crybabies from being offended.
And as far as the web site in question goes, one need only not go there. Or

is that concept too simple for the Thought Police to grasp ?

--
Its not that Liberals are stupid. Its just that they know so much that isn't
so.

Well you're obviously talking about the BBC and I thoroughly agree
with your trenchant observations. However, it appears the attempted
brainwashing has failed, as recent surveys have shown that today's
children are actually *less* tolerant of other races than they were 20
years ago. Perhaps it's a backlash against the overtly obvious
'dysfunctionality is normal' propaganda spewed out by the Corporation
(at public expense, of course).

I would say its more the perception that these minority groups seem to get
more help in many cases to their indiginous white counterparts and they have
this "racial discrimination" cry at them whenever whites repremand or
disagree or voice their own opinion. This rarely used to happen 20 years ago
and we all just got on with it. Nowadays though youngsters and many adults
are fed up with being branded Racist by liberal do gooders and are sick and
tired of being put second place abouve these immigrants/non-indiginous
groups. You can only take so much before you (white people) feel you are the
second class citizen and have to bow to their beliefs and religions
otherwise your branded racist or bigoted.
Then theres the black gangs and the intimidation felt by many which was also
hardly heard of 20 years ago. Also, as said by Enoch Powell many years ago,
forcing different cultures to live with one another will eventually lead to
rivers of blood frowing in the streets. Of course he was branded a screaming
Racist but much of what he warned of is there.

Lets hope so...

Bodies like the Commission for Racial Equality will ultimately
> be the authors of their own downfall. These things, like fashion, go
> in cycles and history has a habit of repeating itself.

As many black and asian people "Use" racism for their own goals, eventually the "cry wolf" scenario will be understood and maybe those who scream they have been racially abused will be found out that they were targeted by something that they did or said rather than the colour of their skin. They will *always* call the race card though. Its a shame it appears to be a one way street though, try complaining that youve been racially abused by a black or asian and nothing seems to happen. Other way round you get arrested and thrown in a cell whether its proved or not.

Its also a well known fact that many of these racism cries like the one to ban Christmas and to call it winterval in Birmingham was laughed at by blacks and asians who had no problems with it at all but it was liberal busy bodies imposing what they thought would constitute bad feeling and upset Jews/muslims etc. Similarly with the St George Flag, these same liberal do gooders accuse it of being a racist flag and try to remove it wherever it is never mind its the Flag of England and banning it only fuells the hatred towards other races even though its not the blacks/asians who are bothered by these things, its the doo gooder busy bodies who look for racism everywhere and impose their beliefs on everyone causing it rather than subduing it.

England is still a mainly white Christian Country.... why dont these idiots remember this and stop pandering to the Libral perceived wishes of the immigrants and those from different races who were born here. They try to make us feel that "English and England" are dirty words.

Don't waste your money on altopia, Caputo has about three days retention on
his servers. Quite possibly the worst nsp on the market.

Yeah, the Today programme on Radio 4 is a peach on St. George's Day.
Those 'presenters' (read "sucklers at the teat of the BBC Milch Cow)
never miss the opportunity to rubbish and ridicule the event. In
recent years, they have (not surprisingly) tried to totally redefine
it to their own twisted standards. One year they even invited
listeners to come up with a new design for the English flag! Bastards.

I have a ham friend who uses long runs of coax to his several towers.
He is a big gun on 80 and 160 meters, so this mainly applies at m-f to
h-f. He uses a lot of LDF5-50 that he obtains in shorter pieces.

His technique, as he briefly described it to me, is to -not- use
connectors but splice the lengths directly. The center conductor on
these cables is hollow, so he inserts a short length of brass or
copper into the ID and solders it in place.

I don't know whether he adds any insulation next or not, but I would
envision injecting some low-expansion spray foam later. He then wraps
the outer conductor with brass or copper foil and solders this in
place. (Here is where I would inject the foam.)

This is then wrapped with tape for protection. I would use a double
layer of #27 3M tape with an overwrap of plastic electrical tape.

To strengthen the joint mechanically, he straps on a length of steel
angle using stainless hose clamps. For lines on or in the ground this
stays in place. For runs up the tower, after the line is in place,

strapping to the tower is sufficient support.

Gosh, Walt, you seem to imagine that most of the people in the USA
gave a rat's ass what you leftist loonies across the Atlantic think of
